CHAPTER 8

Principles of Bone Marrow and Stem Cell Transplantation

W. Nicholas Haining, Christine N. Duncan, Alaa El-haddad, and **Leslie E. Lehmann**

CHAPTER OUTLINE

- **HISTORY AND OVERVIEW**
- **CONDITIONING REGIMENS**
- **SOURCES OF STEM CELLS**
  - Allogeneic Stem Cell Transplantation
  - Autologous Stem Cell Transplantation
- **PERITRANSPLANT SUPPORTIVE CARE**
  - Transfusion Support
  - Nutrition Support
  - Infection Prophylaxis and Treatment
  - Veno-Occlusive Disease of the Liver
- **IMMUNE RECONSTITUTION**
- **GRAFT REJECTION**
- **GRAFT-VERSUS-HOST DISEASE**
  - Acute Graft-versus-Host Disease
  - Chronic Graft-versus-Host Disease
- **ORGAN TOXICITY ASSOCIATED WITH HEMATOPOIETIC STEM CELL TRANSPLANTATION**
- **CLINICAL APPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION**
- **GLOBAL HEALTH AND HEMATOPOIETIC STEM CELL TRANSPLANTATION**

Hematopoietic stem cell transplantation (HSCT) is an accepted treatment for a wide variety of diseases afflicting children, including hematologic malignancies, bone marrow failure syndromes, immunodeficiency disorders, congenital hematologic defects, and select solid tumors. HSCT generally involves a conditioning phase with administration of chemotherapy with or without radiation therapy followed by the infusion of autologous (self) or allogeneic (other) hematopoietic stem cells (HSCs). The conditioning damages the patient's immune system, allowing engraftment of the new stem cells, and, in malignant diseases, can eradicate residual tumor cells, but at the cost of normal organ injury. Patients are profoundly immunocompromised as a result and are at risk for opportunistic infections. These infectious risks, together with other transplant-related complications such as graft rejection and graft-versus-host disease (GVHD) (Box 8-1), and primary disease recurrence have been the main barriers to success in HSCT. However, advances in understanding transplant biology coupled with advances in the supportive care and clinical management of HSCT recipients have made this approach an increasingly attractive modality for a broadening range of indications.

HISTORY AND OVERVIEW

Infusion of bone marrow in an effort to restore hematopoiesis was first reported in 1939 when a patient with aplastic anemia was treated by infusion of a small aliquot of fraternal bone marrow.[1] Subsequently, Jacobson and colleagues demonstrated that shielding the spleen allowed lethally irradiated mice to recover normal hematopoiesis.[2,3] Later, it became clear that the hematopoietic reconstitution of irradiated animals originated from elements in the bone marrow or spleen[4] and that these HSCs could survive cryopreservation and thawing.[5] Investigators subsequently demonstrated that animals could recover only when histocompatible HSCs were infused but suffered from lethal GVHD if given cells from a histoincompatible donor.[6] Better understanding of the essential mediators of the immune response coupled with the observation that administration of methotrexate was effective both in the prophylaxis and treatment of GVHD[7] provided the theoretical and practical tools necessary for HSCT to be attempted in humans.

The first semi-successful attempt at a human bone marrow transplant (BMT) was carried out in 1957 by E. Donnall Thomas, whose body of work in this area was later recognized by a Nobel Prize. These first experiments demonstrated that chemotherapy followed by intravenous marrow infusion could result in a transient graft, although all patients subsequently died of progressive disease.[8] In 1959, lethal doses of total-body irradiation (TBI) and bone marrow from an identical twin were used to in an attempt at transplant in two patients with advanced acute lymphoblastic leukemia.[9] Hematopoiesis

Box 8-1 **Complications of Bone Marrow Transplantation**

SHORT TERM

- Graft rejection
- Infection
- Bleeding
- Acute graft-versus-host disease
- Veno-occlusive disease of the liver
- Idiopathic pneumonitis
- Side effects of radiation therapy, chemotherapy, and immunosuppressive therapy (e.g., radiation nephritis, azotemia)

LONG TERM

- Late graft failure
- Chronic graft-versus-host disease and its sequelae (e.g., bronchiolitis obliterans)
- Pulmonary disorders
- Infection
- Altered intellectual and growth development in children
- Reduced stamina
- Endocrine dysfunction
  - Hypothyroidism
  - Growth retardation (children)
  - Pubertal delay; gonadal failure
- Sexual dysfunction (both sexes)
- Complications secondary to radiation therapy (e.g., cataracts, radiation nephritis)
- Complications secondary to immunosuppressive therapy (e.g., aseptic necrosis of bone, hemolytic uremic syndrome)
- Dental problems
- Psychosocial problems
- Increased risk for second malignancies

was established within weeks, although again both patients experienced relapse and died. The first successful allogeneic HSCT were performed in 1968 and 1969 with the survival of three patients who underwent transplants for congenital immunodeficiencies.[10-13]

HSCT is currently used in a variety of malignant and nonmalignant disorders in which replacement of HSC-derived populations of cells provides or restores normal hematopoiesis or other marrow-derived elements. In malignant diseases, infusion of previously collected autologous HSC significantly shortens the period of myelosuppression and allows for dose escalation as an approach to decreasing relapse rates in malignant diseases. Although bone marrow was initially considered the only source of pluripotent HSC, more recently it has become clear that other sources exist. For example, self-renewing HSC can be collected from umbilical cord blood (UCB). HSCs also circulate in the peripheral blood, albeit in very low numbers; they can be increased after chemotherapy or administration of hematopoietic growth factors and collected as mobilized peripheral blood stem cells (PBSCs). Exploration of the potential for cell populations derived from tissues such as liver, nervous system, and muscle to provide HSCs has been initiated.[14-18]

Reinfusion of a patient's own HSCs after administration of high-dose chemotherapy, radiation therapy, or both is referred to as autologous HSCT. Both tumor contamination and preexisting damage to HSC from prior therapy limit its application. Moreover, the lack of allogeneic immunologic response against any residual or recurrent tumor further impacts success. Despite these limitations, autologous HSCT remains the standard approach to patients with refractory or recurrent lymphoma and other select solid tumors of transplant that demonstrate a response to dose escalation of chemotherapy. In the case of congenital conditions or acquired bone marrow failure syndromes, the abnormalities of the HSCs prevent autologous HSCT from being a meaningful option for most patients. Allogeneic HSCT involves the infusion of HSCs from a related donor (RD) or an unrelated donor (UD). Complications of allogeneic HSCT, such as graft rejection and GVHD, are generally more common or severe with increasing histoincompatibility between donor and host; and a histocompatible sibling, if available, remains the preferred donor. However, it is estimated that only 15% to 40% of patients will have a matched RD.[19,20] Available alternatives include HSCT from an RD that is mismatched[21,22] or from donors in the international UD registries,[23-25] including previously collected and cryopreserved unrelated UCB.[26-28]

Specific conditioning regimens used to prepare patients are reviewed in the next section. In brief, the preparative regimen must reduce or eliminate tumor burden and/or recipient hematopoietic cells and provide sufficient immunosuppression to permit engraftment. Reduced-intensity regimens were developed in the late 1990s to decrease acute transplant toxicity and thus make HSCT possible for a broader demographic. These regimens use intense immunosuppression and harness graft-versus-tumor effect instead of cytotoxicity to address residual malignant cells. Early and late graft failure and relapse remain problematic in this setting. After conditioning, HSCs are infused intravenously into the host; the day of HSC infusion is termed day 0. Neutrophil engraftment occurs 10 to 24 days after infusion, with red blood cell and platelet recovery somewhat more delayed. A number of peritransplant and posttransplant complications influence not only survival but also quality of life after transplant. There is a risk for early graft rejection and for late graft failure. Early complications of HSCT are due to profound pancytopenia, regimen-related toxicity, immunologic reaction of the graft against host tissues (acute GVHD) if the transplant is allogeneic, and protracted immune incompetence. Late complications of HSCT are due to chronic end organ damage from drug and immune insults, ongoing or de novo manifestations of immune dysregulation such as poor immune function or chronic GVHD, and the consequences of disease recurrence.[29] These factors and complications are considered in detail later in this chapter.

Given these obstacles, the evolution of HSCT into a practical and curative therapy has been dependent on a number of important advances. These include an improved appreciation of the human histocompatibility system and development of more exact methods to establish the degree of histocompatibility between the donor and recipient. The ability to deliver the preparative regimen with greater accuracy, as illustrated both by improvements in TBI dosimetry and by the ability to monitor busulfan pharmacokinetics, have contributed to a decrease in regimen-related toxicity. Early and aggressive use of antibiotics, antifungal agents, and antiviral agents and more sophisticated screening for viral reactivation have improved survival during the time of neutropenia and the period of profound and persistent immunosuppression after engraftment. Advances in transfusion support, including viral screening and irradiation of blood products and availability of leukopheresed platelet products, have had enormous impact. Nutritional and other supportive therapies, including the ability to establish long-term vascular access with indwelling lines significantly changed the experience and comfort of HSCT recipients. Although HSCT was originally offered to a small number of patients who had no alternative therapeutic option, improved outcomes due to these and other advances have markedly increased the indications for which populations for whom HSCT can provide benefit. Analysis of registry data suggests that the lifetime probability of undergoing HSCT in the population may reach almost 1% for currently accepted indications if universal donor availability and an increase in the number of eligible patients who actually underwent transplant were to occur.[30] Indeed, given ongoing scientific advances the indications for HSCT and cellular therapies such as gene therapy that utilize a backbone of HSCT are predicted to expand. The increasing population of HSCT patients and HSCT long-term survivors will be best served by improved infrastructure and research into lessening the burden of long term effects.

CONDITIONING REGIMENS

The term *conditioning regimen* refers to the preparative drugs and/or radiation that are administered to an HSCT recipient before the graft is infused. The purpose of conditioning is threefold: first, in the setting of HSCT for malignant conditions, to eradicate any residual malignant cells; second, to be sufficiently immunosuppressive to prevent the immune system of the recipient from rejecting the incoming allogeneic cells; and third, to induce enough marrow aplasia that the donor HSCs have a competitive advantage in reconstituting hematopoiesis. The regimens that are capable of achieving all three goals are usually associated with significant toxicity. Therefore a major goal in HSCT is the development of conditioning regimens that provide an optimal balance between effective myeloablation and manageable toxicity.

The first human BMT by Thomas and colleagues in 1957,[9] and a subsequent experience using UD marrow to treat victims of a radiation accident in Belgrade in 1959,[31] established the basic principle of TBI-based conditioning. Work initiated by Santos, Owens, and Sensenbrenner in the 1960s first demonstrated the use of cyclophosphamide as a conditioning agent.[32] TBI combined with cyclophosphamide has remained the standard conditioning regimen for the past 30 years. More recently, the alkylating agent busulfan has become more widely used as an alternative to TBI, in part because of limited access to costly radiation facilities.[33]

The wide range of indications for HSCT has led to considerable variation in the design of conditioning regimens. For example, high relapse rates after HSCT stimulated attempts to increase antileukemic efficacy of conditioning regimens by employing other high-dose chemotherapy agents in place of or in addition to cyclophosphamide. In contrast, the problem of graft failure/rejection in patients receiving grafts that are T cell depleted or are from genetically disparate donors has led to regimens that increase recipient immunosuppression. Patients with aplastic anemia or with severe combined immunodeficiency (SCID) have preexisting marrow aplasia or immunosuppression, and thus conditioning regimens in these diseases do not require the same degree of ablation as regimens for patients with intact immune function. Similarly, patients with benign hematologic diseases have no need of the antileukemic effect of conditioning, and thus specialized regimens have been developed specifically for these diseases.[34] In addition, as autologous HSC support after high-dose chemotherapy became more common, many new conditioning approaches were developed, emphasizing maximal antitumor effects. Although individual studies demonstrated acceptable or even favorable outcomes related to some of these changes, no consensus as to optimal recipient preparation for either autologous or allogeneic SCT has emerged. More recently, alternative concepts regarding the relative roles of conditioning regimens and the donor immune system in achieving recipient hematopoietic ablation have been applied in a nonmyeloablative approach. Some key issues are highlighted in the next sections.

Total-Body Irradiation

Several parameters associated with TBI can be adjusted to deliver different amounts of radiation and different degrees of end organ effect. Total dose, dose rate, fraction size, interfraction interval, and shielding are among the TBI parameters most manipulated in SCT. An ideal schedule would maximize malignant cell kill, hematopoietic ablation, and, in the case of allogeneic SCT, immunosuppression while limiting acute and chronic toxicity. In principle, higher total dose, higher dose rate, and larger fraction size are associated with greater hematopoietic ablative effect (and therefore potentially greater antileukemic efficacy) and with better immunosuppression. Fractionation, the division of the total dose of radiation over time usually in a twice-daily schedule, theoretically provides improved tolerance for nonhematopoietic tissues, leading to decreased acute toxicity and reduced late effects, but carries the risk for decreased antileukemic efficacy. However, a series of studies from the 1980s supports the use of fractionated radiation, and this remains the standard today.[35,36] Studies from Seattle have demonstrated increased antileukemic efficacy with increased total dose, but lung, liver, and kidney tolerances were limiting.[37,38] Parameters of total dose, fractionation, dose rate, and schedule have been largely extrapolated to pediatric HSCT from adults.[39,40]

Busulfan

Developed in the mid-1970s, busulfan (BU)/cyclophosphamide (CY) rapidly became an established regimen for patients with acute myelogenous leukemia (AML) receiving either allogeneic[41] or autologous SCT.[42-44] The original regimen, called BU/CY4 (“big BU/CY,” BU 4 mg/kg/day

× 4 days followed by CY 50 mg/kg/day × 4 days) was joined by BU/CY2 ("little BU/CY," in which the CY was delivered as 60 mg/kg/day × 2 days),[43-47] and this regimen has been used in patients with acute lymphocytic leukemia (ALL) or chronic myelogenous leukemia (CML).[48,49] The BU/CY regimen has been used extensively in pediatric patients, particularly those with nonmalignant diseases,[50-55] in an attempt to avoid radiation-associated toxicity. The current practice of using an intravenous formulation of BU and dose adjustment to achieve a target level has decreased toxicity; effects on efficacy are more difficult to demonstrate.[56] Treosulfan, a related agent already approved in Europe,[57] has limited nonhematologic toxicity, and pediatric trials are ongoing in national trials.

TBI versus BU

Several randomized studies and meta-analyses have compared BU/CY with TBI-based regimens.[58-66] Overall, results are similar although suggestive that both relapse rates and hepatic veno-occlusive disease (VOD) may be less in the TBI-containing regimens. Although recent data support these observations, variability of the chemotherapy component of TBI-based regimens and potential differences in the antileukemic efficacy of BU/CY4 and BU/CY2 regimens[67] render definitive generalizations difficult. Reports of decreased bioavailability, increased volume of distribution, and increased clearance rate of BU in children raise the question of how to interpret studies in which such data are unavailable.[68-71] Alternative BU dosing, based on plasma levels, has been suggested,[72,73] and comparison of "optimal" BU/CY with CY/TBI has not been reported. BU-containing regimens have often been reported to result in greater toxicity when compared with TBI-based regimens; thus increases in BU dose may further increase regimen-related morbidity.[58,59,61,64,74,75] Monitoring of BU pharmacokinetics has generally, but not always, demonstrated an association of increased area under the curve with increased volume of distribution.[72,76] Individualizing BU dosing may possibly increase the risk-benefit ratio, and the recent availability of an intravenous form of BU with more dependable pharmacokinetics now makes this achievable.[77-79,80]

Alternative Myeloablative Regimens

The addition or substitution of a variety of chemotherapeutic agents to the backbone of CY/TBI, and less commonly BU/CY, has met with mixed success. Etoposide, cytarabine, and BU have been added to or substituted for CY in TBI-based allogeneic regimens.[62,81-88] Etoposide (VP-16) and melphalan have also replaced CY in some BU-based protocols.[89-92] Clofarabine, a purine nucleoside analogue, is a relatively new drug known to be very effective in relapsed/refractory pediatric ALL; ongoing studies have shown promise in using it in combination with BU to decrease relapse in advanced cases of pediatric leukemia.[93] Fludarabine has become an increasingly used drug in allogeneic transplant preparative regimens. It has potent immunosuppressive properties and minimally extramedullary toxicity. Combined with BU (BU/FLU) it provides adequate ablation for full donor engraftment,[94] and in the pediatric population it appears to have similar efficacy but less transplant-related toxicity and faster neutrophil engraftment.[95]

Fluorouracil, high-dose methotrexate, doxorubicin, cisplatin, carboplatin, thiotepa, melphalan, and many other agents have been used in a variety of high-dose chemotherapeutic regimens supported by autologous SCT. Common conditioning regimens referred to by acronyms are CBV (CY, carmustine, VP-16); BACT (BCNU [carmustine], cytarabine [Ara-C], CY, 6-thioguanine); BEAM (BCNU, etoposide, cytarabine [Ara-C], melphalan); and CBP (CY, BCNU, cisplatin). In the allogeneic setting, alternative regimens have generally shown equivalent benefit in terms of disease control but often have increased toxicity. No regimen has established unequivocal superiority in terms of disease-free or overall survival when compared with "standard regimens." Given the more limited follow-up and the extraordinary diversity of diseases and regimens, establishment of relative efficacy in the realm of autologous SCT is likely to be a prolonged process.[96-100]

Nonmyeloablative Regimens

One of the target tissues of allogeneic T lymphocytes is the hematopoietic precursors. As a result, the infusion of donor lymphocytes can be sufficient to cause marrow aplasia. Indeed this is the basis of the marrow aplasia seen in inadvertent cases of transfusional GVHD. Observations made initially in the 1980s by the Seattle group have led to a new approach to conditioning based on the immunologic elimination of normal and malignant hematopoiesis. Because this technique minimizes the doses of conventional conditioning drugs and radiation, it has been called "nonmyeloablative" or reduced-intensity conditioning.[101-107] Although allogeneic graft-versus–bone marrow can cause the necessary marrow aplasia and antileukemic efficacy, it does not supply the immunosuppression needed to avoid graft rejection. This is usually achieved by preinfusion conditioning with purine-analogue chemotherapy and/or low-dose TBI. A variety of agents including lower-dose BU, melphalan, and cytarabine have also been used for additional effect and partial HSC depletion.[101-103,105-107] A major advantage of this approach is that the toxicity of conventional myeloablative approaches can be reduced.[108] Comparisons of conventional versus nonmyeloablative regimens have shown reduced nonrelapse mortality, especially in older adults or patients with preexisting illnesses for whom HSCT is associated with significant toxic death rates.[109,110] The safety and effectiveness of this approach has led to its wider application in recent years. However, the low toxicity of nonmyeloablative regimens is balanced against the increased risk for relapse in acute leukemias and the increased risk for chronic GVHD.[111] The indications for nonmyeloablative transplant may therefore remain principally for slower-growing tumors. Because childhood hematologic malignancies rarely fall into this category, the use of nonmyeloablative transplant in children has been more limited.[103,112,113] Moreover, the increase rates of graft rejection after standard HSCT for nonmalignant conditions such as thalassemia and sickle cell anemia have precluded the broad use of nonmyeloablative transplants in these conditions.

SOURCES OF STEM CELLS

Selection of an appropriate source of HSCs for the patient undergoing HSCT is a complex undertaking. HSCs can be obtained from the bone marrow, peripheral blood, or the umbilical vein of neonates. The majority of HSCTs in the pediatric setting are performed from allogeneic donors, but autologous peripheral blood is also used as a stem cell source for transplants, particularly in patients with solid tumors. For each disease entity, the clinician must consider what sources of stem cells are available and the relative risks and benefits associated with each potential stem cell source. For allogeneic donors, the principal consideration in donor selection is the genetic similarity between donor and recipient.

Typing

Genetic disparity between host and donor can lead to graft rejection or GVHD. The genes encoding the antigens most associated with these complications lie in a group of genes known as the major histocompatibility complex (MHC). In humans, the MHC maps to a region of the short arm of chromosome 6, known as the human leukocyte antigen (HLA) system. The MHC codes for many genes are still being identified, and the exploration of the functional importance of some of these gene products is still ongoing. Among the best characterized gene products are proteins comprising the class I and class II antigens. In humans, MHC class I molecules include HLA-A, HLA-B, and HLA-C and MHC class II molecules are called HLA-D. There are at least five subregions, including DR, DQ, and DP, but the number of genes transcribed differs between different HLA class II haplotypes.

The MHC class I antigens are present on nearly all human cells (with rare exceptions such as the erythrocyte and corneal endothelium). MHC class II antigen expression is more restricted, with expression limited to "professional" antigen-presenting cells, including dendritic cells, B cells, monocytes, macrophages, and Langerhans cells. Class II antigens can also be induced on activated T cells and endothelium. MHC genes are codominantly expressed, that is, each parent contributes half of the MHC antigens expressed on each cell of their offspring. MHC class I and II antigens normally function to present partially degraded products of intracellular proteins to T cells. In this way, damaged or virally infected cells can be identified by the immune system. However, in the setting of transplantation, the recognition of MHC molecules by T cells is known as alloimmunity and is the basis for GVHD and graft rejection.

The genes of the MHC region are highly polymorphic, and less than 30% of potential recipients of HSCs have HLA-identical siblings. Moreover, even HLA-identical sibling transplants can be associated with GVHD because of differences in the sequence of the intracellular proteins associated with MHC molecules caused by polymorphisms in non-MHC genes. These polymorphisms are mostly unidentified, and those that are known to elicit alloreactive T-cell responses are termed *minor histocompatibility antigens*.[114] Although these antigens may not be directly responsible for organ and bone marrow rejection, human typing studies suggest that these minor antigens contribute to the generation of GVHD.[115,116]

Historically, HLA typing was performed by using antibodies derived from postpartum sera, from persons who have undergone transplants or transfusions, or even from persons immunized for the purpose of generating specific serologic reagents. These antibodies were used in a standardized complement-dependent, microcytotoxicity assay with purified T or B lymphocytes as their target cell.[117] The extensive cross-reactivity among products coded by the alleles of the HLA-A and HLA-B loci, known as cross-reactive groups, made precise delineation of the MHC class I antigens by this technique difficult. In contrast, HLA-D specificities were originally defined by their ability to stimulate T-lymphocyte proliferation in a mixed leukocyte culture.[118]

Because of the difficulty in precise delineation of HLA-type by serologic methods, modern HLA typing now uses high-resolution techniques that resolve the DNA sequence of specific alleles. The first attempts to use molecular genetic techniques were based on application of restriction fragment length polymorphism analysis of genomic DNA by Southern blotting using HLA region probes. This soon gave way to current technology in which sequence-specific oligonucleotide probes and, in some cases, direct sequence analysis are performed. This has also led to a great increase in the number of identified HLA specificities. This fine analysis is increasingly being used to determine the haplotypes of patients and potential donors. The implications of more exact typing within families, where the haplotypes are "conserved," are probably confined to the potential identification of minor histocompatibility antigen differences, allowing for better selection between possible donors.[115,116,119] In the UD setting, high-resolution HLA matching has significantly contributed to the improved outcomes reported in UD HSCT in the past decade.[120,121,122] Historically, an allogeneic donor must match the patient at five of the six major loci (e.g., A, B, DR) for a transplant to be feasible. Stem cells obtained from UCB are more permissive, and four of six matches are acceptable.

Allogeneic Stem Cell Transplantation

Most allogeneic transplants use HSCs from a matched sibling donor. However, with improvements in immunosuppression and ability to prevent or treat GVHD, UDs, UCB, and partially MHC-mismatched family donors are now increasingly used as sources of HSCs. There are now approximately 16 million UDs listed in over 72 registries worldwide, including registries of banked UD UCB collections.

The selection of an allogeneic HSC source is dependent on many variables. In malignant disease, the ease and speed with which a stem cell source can be obtained are important factors. For patients with aggressive malignancies, being able to proceed rapidly to transplant is particularly desirable. Increasing genetic disparity between donor and host—termed *histoincompatibility*—has historically contributed to both an increased rate of graft rejection and severe acute and chronic GVHD and is a critical factor in the choice of donor. Even in the setting of HLA-identical siblings, selection can be further refined according to donor gender and age, history of donor parity, donor infectious disease status, and other variables, all of which can contribute to the success of transplant.

For the majority of patients who do not have a matched sibling donor, potential sources include a family member who is phenotypically adequately matched at the HLA loci but is genotypically distinct or a volunteer UD donor who shares the majority of HLA alleles with the recipient. The likelihood of locating an appropriate UD donor is dependent both on the patient's ethnicity (in as much as it determines histocompatibility antigen and haplotype frequency) and on the composition of the donor pool. For example, for whites of mid- and northern European descent the likelihood of finding a six-antigen matched UD approaches 50% to 70%.[123] In contrast, the extreme genetic heterogeneity of the African-American population coupled with underrepresentation of this population in volunteer registries makes the likelihood of finding a similar matched donor 10% to 15%. Molecular typing techniques demonstrate that the allelic disparities in both whites and nonwhites is much higher than previously expected, thus making the ascertainment of truly "matched" UD less likely even as the donor pool expands.[124] Although the implications of specific HLA mismatches are incompletely understood, most studies suggest that high-resolution HLA matching is associated with improved outcome in UD HSCT.[120-122,125] Thus additional strategies to broaden the donor base by using alternative HSCs such as UCB that exhibit different biologic properties and allow greater HLA disparity have allowed for more patients with uncommon typing to find an acceptable donor.

Sources of HSC

In the past, most HSCT has used bone marrow mononuclear cells as a source of HSCs. Bone marrow is usually obtained by repeated aspiration of the posterior iliac crests while the donor is under general anesthesia. Multiple aspirations are performed to a total volume of 10 to 15 mL/kg recipient body weight. The marrow is filtered through a fine wire mesh to rid the product of aggregates and bony spicules. This is a surprisingly well-tolerated procedure and serious complications are rare, probably because the donor is generally a healthy individual undergoing an elective procedure. Potential short- and long-term complications include risks of anesthesia, blood loss and potential transfusion, pain, neurologic deficits, and psychosocial complications. In the most truly altruistic setting, UD marrow harvest, only 5% to 8% of donors later expressed any ambivalence about their participation. This was most marked if the transplant was subsequently unsuccessful.[126] Once harvested, the red cells must be removed from the bone marrow if there is ABO incompatibility before infusion into the recipient.[127] The marrow may be manipulated ex vivo to remove donor T lymphocytes (see later) or tumor cells. It is estimated that only 1% of the donor pluripotent HSC population is removed in a typical marrow harvest.

HSCs continuously recirculate from the marrow into the peripheral blood; therefore HSCs can also be harvested by collection of peripheral blood mononuclear cells, usually by leukapheresis. The frequency of cells that express the surface marker CD34 is widely used as a proxy for actual HSC frequency and allows the enumeration of stem cells. HSCs in the peripheral blood are rare, and granulocyte colony-stimulating factor (G-CSF) is usually administered to increased the detachment of HSCs from bone marrow niches and promote their egress into the peripheral blood, increasing their frequency.[128-132] Moreover, studies in adults suggest that additional strategies to further mobilize marrow HSCs are possible. AMD3100 is a reversible inhibitor of the CXC chemokine receptor (CXCR4), a receptor on the surface of HSCs that promotes adhesion to the bone marrow milieu. Combining AMD3100 with G-CSF increases HSC yield in adults,[133] but this approach has not been investigated in children. Complications of PBSC harvest have included bone pain, as a side effect of G-CSF, and inability to collect via peripheral access, necessitating central line placement.[134,135] There is an increased risk for splenic rupture resulting from G-CSF administration in healthy individuals, although this is an extremely rare complication.[136] The implications of mobilizing and harvesting PBSCs from pediatric donors have not been fully explored,[137,138] although cytopenias and hemostatic changes of unknown short- and long-term significance have been observed in healthy donors.[139,140]

Since the first description of its use in a child with Fanconi anemia in 1988,[141] UCB has become an increasingly used HSC source. Placental blood is recovered from the umbilical vein by drainage or catheterization, and techniques to optimize UCB HSC collection are being investigated.[27,142] Cord blood is immediately frozen and stored until needed. If indicated, in the related setting, determination of the HLA type of the fetus can be performed before delivery. Otherwise, typing and analysis is performed on intrapartum or postpartum samples.

Selection of a UD, whether bone marrow or UCB, is facilitated by the availability of epidemiologic information (e.g., age, sex) as well as HLA typing stored in a database accessible via the Internet. By comparing a patient's HLA type with donors listed and categorized in the registries, one can estimate the likelihood of a successful search, devise search strategies for patients with uncommon HLA types, and sort among potential HSC sources. Although stored UCB can be readily supplied after confirmatory typing, the completion of a UD bone marrow donor search is more involved. Potential donors must be contacted and consent to proceed, and the donor center must arrange for appropriate confirmatory studies and medical and other evaluations and schedule the harvest. The time from formal search to BMT averages 4 months for UD, whereas compatible UCB, where typing occurs at time of cryopreservation, can be found in days to weeks.

Engraftment

After allogeneic HSCT, donor stem cells must expand to repopulate hematopoietic niches and differentiate to form mature blood cells. HSCT recipients show accelerated telomere shortening in peripheral blood cells, which is presumably due to increased replicative demand for donor stem cells.[143] Donor hematopoietic engraftment after allogeneic HSCT can be documented both by analysis of chimerism as well as by the recovery of peripheral blood cell counts. However, sensitive DNA amplification technologies have demonstrated residual host hematopoiesis for variable periods of time, certainly up to 1 year.[144-146] Mixed lymphoid chimerism is also well documented.[144-147] The implications of mixed chimerism with respect to subsequent relapse remain controversial, probably because the current extremely sensitive assays generate data that are difficult to interpret uniformly and because outcome may well differ by disease type.[148] For example, chimerism after BMT for CML is quite reliably related to subsequent relapse while this may not be true for other diseases.[147-149]

The rate and probability of engraftment after allogeneic BMT varies with the source of HSCs, the number of HSCs given, the extent of preinfusion cell manipulation, and the GVHD prophylactic regimen used. In general, neutrophil recovery is achieved within 2 to 3 weeks and platelet recovery occurs 1 to 2 weeks thereafter. PBSC transplants are associated with a more rapid rate of engraftment than with bone marrow, most likely a result of the higher CD34+ cell dose obtained.[150] Neutrophil engraftment occurs between 1 and 6 days earlier with PBSC transplant than with BMT and platelet engraftment between 4 and 7 days earlier.[151] Neutrophil and platelet engraftment after UCB transplantation is significantly delayed in comparison with that seen in other stem cell sources.[152-156] It is a consequence of the lower nucleated cell and CD34+ cell dose in UCB products. This has limited the application of this modality in adults, and currently using two unrelated UCB units for a given patient is being studied.[157]

The use of methotrexate as GVHD prophylaxis is associated with delay in count recovery; conversely, recovery after T-cell–depleted BMT is more rapid. Use of colony-stimulating factors after BMT is associated with more rapid neutrophil recovery after related BMT, a finding confirmed in small pediatric series.[147-149,158-163] No change in platelet recovery has been noted. Interestingly, preliminary data do not show any colony-stimulating factor–mediated acceleration of engraftment in patients undergoing UD BMT.[163]

The number and quality of T cells that are present in grafts from peripheral blood, bone marrow, and UCB confer different rates of GVHD. GVHD, particularly chronic GVHD is more frequent in PBSC transplant than in bone marrow–derived HSCT, although this risk may be offset by an increased graft-versus-leukemia effect.[164] In adults this increased rate of GVHD has not diminished the efficacy of PBSC transplant. However, in children, PBSC transplant has been associated with a worse outcome than when bone marrow is used as a cell source.[165] The precise indications of PBSCs versus bone marrow as a source in pediatric HSCT therefore remains to be defined. Conversely, the rate of GVHD in UCB is lower than with either PBSC or bone marrow sources and allows for less stringent HLA-typing requirements.[166]

Autologous Stem Cell Transplantation

The fundamental rationale supporting autologous HSCT is that very high doses of cytotoxic agents (dose intensification) increase tumor cell death and that a high-dose treatment regimen can be devised in which the major dose-limiting toxicity is myelosuppression. This toxicity can be ameliorated by infusion of previously collected and cryopreserved autologous stem cells obtained either by bone marrow harvest or by apheresis of peripheral blood. Using autologous cells to support and reconstitute the host after aggressive ablative or near-ablative therapy has been most thoroughly explored in both Hodgkin and non-Hodgkin lymphomas, less well developed in acute and chronic leukemias, and still considered experimental, albeit relatively widely applied, for a growing number of pediatric and adult solid tumors. As well, the relative merits and demerits of each autologous cells collected peripherally or from marrow are still not firmly established.

Contamination by Tumor Cells

A major limitation of autologous HSCT remains contamination of the stem cell product with residual malignant cells. Although the relative contributions of either residual tumor within the host or tumor reinfused with stem cells to subsequent relapse remain unknown, increasing evidence from gene-marking studies suggests that reinfused cells contribute to relapse.[167] In addition, in vitro assays of tumor cell colony formation and minimal residual disease (MRD) detection by polymerase chain reaction suggest that contamination of the stem cell source by tumor cells is associated with an increased relapse rate after HSCT.[168] No large randomized clinical trial of PBSC versus bone marrow with respect to disease-free survival (DFS) has been reported. However, paired samples of PBSCs and bone marrow have been examined in a variety of settings (e.g., breast cancer, non-Hodgkin lymphoma) in which PBSCs have revealed lower levels of tumor cell contamination in the steady-state setting.[169] More recent data suggest that the advantage of PBSCs may be abrogated after mobilization,[170-174] although impact on DFS remains unclear.

A variety of methodologies have been developed to eliminate, or purge, tumor cells from stem cell collections. These are based on either positive or negative selection. The major clinically applied positive selection strategy is that of stem cell enrichment, most often selection of CD34+ cells. Negative selection is based on technologies that deplete tumor cells to a greater degree than normal stem cells. Strategies include the use of pharmacologic agents (e.g., mafosfamide), immunologic reagents targeting tissue specific antigens (e.g., neural crest antigens in neuroblastoma), and manipulation of physical or culture properties of cells. Combinations of both negative and positive selection strategies may improve both the yield and purity of stem cell collections.[175,176] Increasing evidence in multiple clinical settings demonstrates an association between minimal residual tumor contamination and relapse[168] and, conversely, suggests that more effective purging strategies may be associated with improved DFS. However, randomized studies comparing purged and unpurged stem cells have yet to be reported.

Engraftment

Trilineage hematologic reconstitution has been achieved after the infusion of autologous bone marrow, after bone marrow and PBSCs, and after PBSC infusion alone. The most mature studies are of patients reconstituting hematopoiesis with autologous marrow where engraftment after bone marrow infusion is both reliable and durable; durability of PBSC-reconstituted hematopoiesis, undertaken more recently, is less fully evaluated. The best predictor of engraftment and rate of hematologic recovery has not been established. Although colony-forming units, burst-forming units-erythroid (BFU-E), nucleated cell count, and other measures have correlated with time to engraftment in some studies, correlations have not been universal and may additionally depend on the patient population, method of cell procurement, and subsequent cell manipulation. CD34+ counts have emerged as the most reliable and practical method for predicting engraftment after PBSC infusion, with retrospective analyses demonstrating that the risk for graft failure is substantially higher in patients who received less than 2×10^6/kg CD34 + cells per kg.[177-179]

Reconstitution of hematopoiesis after autologous bone marrow infusion has shown some tendency to be delayed when compared with the allogeneic setting. This delay is presumed due to the extent, nature, and duration of prior therapy. In addition, cell manipulation ex vivo (purging) may also contribute to delayed engraftment. Reconstitution after HSCT with autologous bone marrow can be hastened somewhat by the addition of hematopoietic growth factors to the post-SCT supportive care regimen, although the extent and nature of prior therapy may limit response to growth factors. Preliminary information in both the preclinical and clinical arenas suggests that prior aggressive chemotherapy may limit potential for hematologic recovery.[180-182] Prior intensive chemotherapy supported by use of growth factors may also contribute to poor engraftment after autologous transplantation. In fact, despite recovery of peripheral blood counts, hematologic marrow reserves as assessed by in vitro measures of hematopoiesis may be blunted for many years after autologous HSCT.[183]

Addition of mobilized PBSCs to bone marrow has resulted in a dramatic decrease in days of neutropenia and thrombocytopenia in most series with or without subsequent growth factor support. Further, use of mobilized PBSCs as the sole stem cell source has been almost universally associated with more rapid hematologic recovery. It is still debatable whether the use of hematopoietic growth factors in this setting further enhances the rate of engraftment, but available data suggest that it may. Whether the process of PBSC transplantation will result in durable hematopoiesis over decades is not yet evaluable, but reports of late graft failure are rare. Most studies suggest that the increased rate of engraftment observed with PBSCs results in decreased days in hospital, use of antibiotics, and associated supportive services. The overall impact of PBSCs versus bone marrow as a stem cell source on the outcome or cost of transplantation has yet to be determined.

Myelodysplasia Syndrome as a Late Complication

Chemotherapy, particularly with alkylating agents, may result in an increased risk for subsequent myelodysplasia syndrome (MDS). Many patients who come to autologous transplantation have received treatment with such agents. Over the past several years, increasing numbers of patients developing MDS after autologous transplantation have been reported, usually occurring from 4 to 7 years after HSCT.[184] The actuarial incidence ranges from 5% to 10% in most series,[185-187] although it has been reported to be as high as 18% at 5 to 6 years after HSCT in single center experiences.[188,189] Identified risk factors have included etoposide use for stem cell mobilization,[187] conditioning regimens utilizing TBI,[185,190,191] and the amount of chemotherapy received before HSCT and/or the interval between diagnosis and HSCT.[191,192] Whether the MDS results from previously damaged reinfused hematopoietic cells or from residual hematopoietic cells sustaining further injury during conditioning is unresolved. Cytogenetic analysis of bone marrow before autologous HSCT can reveal preexisting abnormalities and should be a standard component of pre-SCT evaluation.[193] However, most patients developing MDS have been reported to demonstrate normal cytogenetics at the time of transplant.[186] With more sensitive techniques currently available, such as fluorescence in situ hybridization, the majority of patients developing MDS post-SCT have been shown to harbor the same cytogenetic abnormality in pre-SCT specimens.[194] Similarly, using an X-inactivation–based clonality assay in female patients, clonal hematopoiesis was demonstrated in a small percent of patients before HSCT; those patients were at significant risk for developing MDS after HSCT.[184] This suggests that many cases of post-SCT MDS evolve from an abnormal clone already present before HSCT. The appropriate evaluation of hematopoietic status before embarking on autologous HSC collection and transplantation requires further study.

Immune Reconstitution

The period after HCST is characterized by profound immunodeficiency, and death from infectious complications is a major obstacle to the success of transplantation. Myeloablative conditioning results in the wholesale loss of immune cells that are necessary to confer protective immunity, including T, B, and natural killer (NK) cells. Although hematopoiesis can return within weeks of transplant, recovery of a functional immune system can take much longer and the risk for opportunistic infection remains high for up to a year even in uncomplicated transplants.

The degree of immunodeficiency varies with time, reflecting different contributions of donor and recipient immune function at different stages after transplant. Mature T, B, and NK cells are present in the donor inoculum of bone marrow, peripheral blood, or UCB and can contribute to some degree of host immunity in the immediate posttransplant period. The ability of these transferred cells to provide immune protection is dependent on how immunologically "experienced" the donor is. For instance, recipients of grafts from donors who are immune to cytomegalovirus (CMV), that is who have previously been infected with the virus and have mounted a protective immune response, have a lower rate of CMV disease, presumably because of transferred immunologic memory to that virus.[195] Similarly, recipients whose donors have been vaccinated with a pneumococcal vaccine respond to pneumococcal vaccines more rapidly and with higher antibody titers after transplant, again suggesting that donor immunity can be transferred to the recipient.[196] However, full immune reconstitution, with the ability to mount a protective immune response to new pathogenic challenges, is dependent on the differentiation of new immune cells from precursors in the donor graft inoculum.

In most patients, NK cells are the first lymphoid population to recover. In the first month after transplant, NK cells can represent the main lymphoid cell in the peripheral blood. T cells recover much more slowly, and normal numbers of CD4 and CD8 T cells are not achieved for 6 to 12 months after HSCT.[197] The delay in T-cell neogenesis is because the development of new T cells is a complex process that takes months to complete. During the early period after transplant, T cells with a naïve phenotype predominate in the peripheral blood, suggesting repopulation of the T-cell compartment with recent thymic emigrants.[197-199] Increased thymic output contributes to the expanding peripheral T-cell pool after transplant for 12 to 24 months after HSCT.[200] This thymic output occurs even in adult patients whose thymuses have presumably involuted. The rate of increase in T cells is usually much more rapid in pediatric HSCT patients, consistent with the presence of more robust thymic function.[197] The advantage of a functional thymus in immune reconstitution has been demonstrated by the marked decrease in the fraction of naïve peripheral blood T cells in a 15-year-old HSCT patient who had had a previous thymectomy compared with thymus-bearing HSCT patients.[201] By using quantitative molecular measures of T-cell repertoire, several studies have shown that it can take as long as 12 to 24 months after HSCT for a full range of T-cell receptor diversity to be present in the T-cell compartment.[198,199,202] This underscores the critical role of naïve thymic emigrants in restoring the full complement of T-cell receptor specificities.

Several factors influence the length of time that immunologic recovery takes. Age of BMT recipients profoundly affects the rate of immune reconstitution, with an inverse correlation between recipient age and the absolute number of T cells 1 year after HSCT.[203] Using mobilized PBSCs as a source of stem cells appears to be associated with a faster rate of recovery than using HSCs from bone marrow, possibly as a result of a larger cell dose.[129,204] Increasingly intensive conditioning regimens are delaying immune recovery in autologous recipients to a degree comparable with allogeneic HSCT.[203] Although hematopoietic engraftment appears to be delayed in UCB recipients, immune reconstitution in children after UCB HSCT is comparable to those receiving unrelated BMT.[205] The presence of GVHD can significantly delay immune reconstitution both as a result of disruption of normal T-cell development and from the added immunosuppression that is required for management of the disease.[206] The consequence of factors that delay immunologic recovery is significant: slow recovery of immune function is associated with an increase in the cumulative incidence of infections and nonrelapse mortality.[129,207]

PERITRANSPLANT SUPPORTIVE CARE

Transfusion Support

Virtually all patients undergoing HSCT require red blood cell and platelet transfusions during transplant, and some patients require transfusions for several months after transplant. All blood products should be gamma irradiated to prevent transfusion-induced GVHD that can result from donor T lymphocytes in the cellular product.[208,209] Multiple processes including psoralens photochemical treatment and leukocyte filtering have been investigated for prevention of transfusion-associated GVHD, but gamma irradiation remains the standard of care.[209-214] Additionally, it is recommended that blood products are either filtered to achieve white blood cell reduction or CMV seronegative. Prior studies indicated that leukocyte-reduced blood products are equivalent to CMV-seronegative blood products for the prevention of transfusion-transmitted CMV.[215,216] However, a meta-analysis of the available literature suggests that the risk for transfusion-transmitted CMV is greater with white blood cell–reduced blood products when compared with CMV-seronegative products.[217]

Whether platelet and red blood cell transfusions should be given prophylactically during the period of cytopenia remains an area of controversy. There are no studies in the modern transplant era evaluating the use of prophylactic platelet transfusion compared with therapeutic transfusions. More recent studies have addressed different therapeutic triggers for prophylactic transfusions, specifically 10×10^9/L versus 30 or 20×10^9/L.[218,219] A review of studies of prophylactic platelet transfusion triggers found no statistically significant differences between groups with regard to mortality or severe bleeding events.[220] Although no statistical significance was found, these studies were small and no recommendations can supplant the need for clinical judgment in individual situations.

Nutrition Support

Provision of nutritional support during HSCT requires an appreciation of the metabolic needs of the individual patient, which is influenced by the body composition and complications of transplant. Patients who are underweight have been shown to be at an increased risk for death compared with patients of normal weight in the early period after transplant.[221] The impact of obesity on transplant outcome is debated, with some studies noting no effect and others reporting lower survival in obese patients.[221-223] Both the direct effects of conditioning regimens (e.g., mucositis) and complications of HSCT (e.g., GVHD, VOD, infection) can induce gastrointestinal damage that compromises the nutritional status of HSCT patients. Enteral feeding has been shown to be effective and safe and to have fewer complications than parenteral nutrition during HSCT but is not always practical for children.[224-228] Several studies have demonstrated the efficacy of parenteral nutrition when enteral nutrition is no longer possible.[229-231] However, in addition to expense, parenteral nutrition has attendant potential complications, including vascular access difficulties, abnormal liver function, and episodes of hyperglycemia and hyperlipidemia. A review of literature does not support the uniform use of parenteral nutrition as nutritional support during HSCT.[232,233] The authors propose that the use of parenteral nutrition be reserved for patients unable to tolerate enteral feeding. Some patients may be able to maintain their nutritional needs orally throughout transplant, and both enteral and parenteral nutrition routes may be used on occasion. Resumption of enteral feeding should be encouraged, and continued monitoring of nutritional intake and weight is necessary not only through engraftment but also after discharge from the hospital. Malnutrition appears to be relatively frequent after HSCT, and even patients with no or limited GVHD may have significant nutritional problems.

INFECTION PROPHYLAXIS AND TREATMENT

Infection risk is greatest in the allogeneic and T-cell–depleted settings, where, despite phenotypically normal circulating lymphocytes, cellular immunity is depressed for at least 1 year after HSCT.[234,235] Guidelines for infection prophylaxis and treatment are published regularly by the American Society of Blood and Marrow Transplantation[236] and provide a standard approach to an ever-evolving area.

Viral infections, both newly acquired and reactivating from a pre-HSCT exposure, present a major risk to patients. Both CMV-seropositive patients and CMV-seronegative patients who have received grafts from seropositive donors are at risk for CMV, although the risk for reactivation is greatest for seropositive recipients with a seronegative donor, owing to patient reactivation of latent virus in the context of naïve donor T cells.[237,238] A large multicenter trial found that patients receiving a UD HSCT from CMV-positive donors had an improved overall 5-year survival compared with patients receiving cells from CMV-negative donors.[239] T-cell depletion abrogated this effect, which suggested that the improved survival was due to transfer of donor immunity. The clinical manifestations of CMV after HSCT include pneumonia/interstitial pneumonitis, colitis, hepatitis, and CMV-related cytopenias. Before the use of ganciclovir for CMV prophylaxis and treatment, more than a third of allogeneic SCT patients developed CMV infections.[237] Almost 20% developed pneumonia, with a mortality rate of 85%.[237] With the availability of effective antiviral therapies, almost all patients at risk for CMV disease receive prophylaxis during the HSCT admission. Randomized studies have found acyclovir, valacyclovir, and ganciclovir prophylaxis initiated at engraftment to be effective at reducing CMV disease before day 100.[240-243] The use of prophylactic acyclovir has been shown to decrease overall mortality for at-risk patients.[244,245] These studies found that the use of prophylactic ganciclovir after engraftment was limited by drug-induced cytopenias and other toxicities. There are multiple studies of preemptive CMV treatment based on the results of positive culture, polymerase chain reaction assay, antigen testing, or bronchoalveolar lavage fluid evaluation.[246-249] A review of the published CMV literature since 1995 found no advantage to prophylactic treatment over preemptive treatment in response to screening tests.[249] Additionally, this review found that preemptive therapy based on polymerase chain reaction tests or antigen assay was superior to culture or bronchoalveolar lavage–based strategies. Both ganciclovir and foscarnet are considered to be first-line therapy for CMV reactivation or treatment of disease.[250] Ganciclovir and foscarnet are similar in efficacy and primarily differ in terms of side-effect profile.[251] CMV-seropositive patients undergoing autologous HSCT have not generally received either screening or prophylaxis,[250] although CMV disease occurs in a small percent of these patients.

Up to 50% of patients undergoing either autologous or allogeneic HSCT experience varicella-zoster virus reactivation, usually within the first year after SCT.[252] The vast majority of patients respond to acyclovir treatment. In children, the onset may be earlier, with fewer cases of visceral involvement. In general, pediatric patients respond well to antiviral therapy and fatalities are rare.[253,254] Treatment with acyclovir for 1 year after HSCT is the current recommendation for any patients with a pre-HSCT history of varicella infection.[255] Varicella vaccination is currently considered optional after autologous or allogeneic HSCT. A pilot study of the live-attenuated vaccine in autologous patients found the vaccine to be safe, but efficacy data are still pending.[256]

Fungal infection remains a significant problem, especially in those receiving corticosteroids for treatment or prophylaxis of GVHD. A randomized trial demonstrated that administration of prophylactic fluconazole for 75 days after allogeneic HSCT yields ongoing protection against disseminated candidal infections and improved survival.[257] However, prophylactic fluconazole has been associated with the emergence of resistant species such as *Candida krusei*.[258] Low-dose amphotericin B has also been used prophylactically and is as effective as fluconazole but more toxic.[259] The use of liposomal amphotericin has improved the toxicity profile.[260] Voriconazole has a broader spectrum of antifungal activity than fluconazole, but a randomized trial comparing the two agents as prophylactic therapy failed to show a survival difference in allogeneic HSCT patients.[255]

All HSCT patients are at risk for the development of *Pneumocystis jirovecii* after transplant. Standard practice is to administer prophylaxis to recipients of autologous HSCT for 6 months after day 0 and for 6 months after discontinuation of immunosuppression for recipients of allogeneic transplant.

Veno-Occlusive Disease of the Liver

Veno-occlusive disease, also known as sinusoidal obstruction syndrome, is a clinical syndrome occurring in the early posttransplant period and characterized by hepatomegaly, right upper quadrant pain, jaundice/increased bilirubin level, and fluid retention.[261-263] VOD can occur after either autologous or allogeneic SCT[262,264-266] and results from chemotherapy/irradiation-induced damage to endothelium and hepatocytes.[262,265,267,268] Injury to the sinusoidal endothelial cells and hepatocytes in zone 3 of the liver acinus appears to be the initial event, resulting in subendothelial edema and endothelial cell damage and subsequent microthromboses, fibrin deposition, and the expression of factor VIII/vWF within venular walls.[269] Later features include collagen deposition within venular lumens with eventual luminal obliteration and hepatocyte necrosis.[267,270,271] Identified risk factors for developing VOD include previous chemotherapy regimens containing gemtuzumab ozogamicin, BU-based conditioning regimens (especially when combined with CY and methotrexate), prior intensive chemotherapy (as seen in advanced-stage malignancies), total parenteral nutrition for more than 30 days, and transplantation from UDs.[264,265,270,272-281] Pretransplant iron overload may also potentiate the development of VOD, and a pre-HSCT ferritin level of more than 1000 is an additional identified risk factor in some studies.[282]

The first clinical signs of VOD are hepatomegaly and right upper quadrant pain with fluid retention, typically occurring 10 to 20 days after chemotherapy administration.[265] Other clinical signs include hyperbilirubinemia, peripheral edema, ascites, sodium avidity, and pulmonary infiltrates/effusion/edema.[262,265] Patients with VOD are at increased risk for developing renal insufficiency and failure.[265,283] It is hypothesized that portal hypertension from sinusoidal injury leads to decreased renal perfusion and tubular injury, resulting in renal damage.[265,283,284] Hepatorenal syndrome occurs in approximately half of patients with severe disease[265] and is associated with changes in mental status.

It is essential to exclude other causes of liver disease (e.g., sepsis, portal vein thrombosis) before a diagnosis of VOD can be made. Liver biopsy is the gold standard for diagnosis and along with hepatic venous pressure measurements can still provide valuable diagnostic information, although it is associated with considerable morbidity in this critically ill population.[285,286] Doppler ultrasonography can help confirm the diagnosis, but classic findings are not always present early in course of the disease. If clinical concern is high, repeating the ultrasound evaluation after several days may be helpful.[287,288] However, the presence of ascites, gallbladder wall thickening, hepatomegaly, decreased or reversed flow in the portal vein, and increased mean hepatic artery resistive index are support of the diagnosis.[262,287-291] Recent clinical guidelines suggest that clinical criteria are sufficient to make the diagnosis while ultrasonography or liver biopsy can be reserved for cases with high levels of diagnostic uncertainty.[292]

Reported overall survival rates for pediatric patients with established VOD range between 53% and 100%.[264,273,279,280,293-296] Predictors of mortality in children with VOD include the use of allogeneic donors other than a matched sibling, concomitant moderate-to-severe hepatic or cutaneous GVHD, and higher VOD severity (e.g., higher peak bilirubin, higher maximal weight gain, presence of pleural effusion, requirement for intensive care unit admission).[264,273]

Treatment and prophylactic options for patients with VOD have evolved over the past decade. The most straightforward preventative technique is to identify patients at highest risk and to consider alternative conditioning regimens when feasible.[261-263] Ursodeoxycholic acid has been used as a preventative agent with inconclusive results.[297-303] Other strategies such as the use of fresh-frozen plasma, prostaglandin E_1, *N*-acetylcysteine, and antithrombin III are potentially effective but require further study before being considered a standard approach.[304-311] Because the majority patients can recover spontaneously, supportive care with meticulous fluid and blood product management remains the mainstay of therapy for moderate VOD.[312] Based on histologic observations of microthrombi and fibrin deposition coupled with laboratory evidence of abnormalities in the coagulation cascade, many therapeutic strategies have been directed at promoting thrombolysis or fibrinolysis.[311,313-317] Multiple small studies have investigated the use of thrombolytic agents and anticoagulants (typically tissue plasminogen activator and heparin) for VOD prevention and/or treatment.[311,313-315,318,319] Although these strategies appear to be generally safe, they have not shown significant reduction in the incidence or outcome of patients with severe disease and have been associated with serious bleeding in some cases.[304,313-315,320-327]

Defibrotide is a single-stranded polydeoxyribonucleotide that has antithrombotic and thrombolytic activity. It has been demonstrated to be effective with minimal toxicity for both the prevention and treatment of VOD.[292,328-334] The mechanism of action is unclear, but it appears to promote angiogenesis and promote sinusoidal endothelial regrowth and has thrombotic/thrombolytic properties.[335] Defibrotide prophylaxis has been shown to be safe in adults and children; efficacy in preventing VOD has been demonstrated in small studies, but there is still a paucity of large studies or randomized trials.[336,337] Response rates between 35% and 50% have been reported for patients with severe VOD treated with defibrotide, and it is not associated with increased risk for major bleeding.[331,338-340]

Refractory VOD portends poor outcome with limited therapeutic options. Liver transplant has resulted in clinical improvement in about 30% of the small numbers of patients stable enough to undergo the procedure; the immediate- and long-term issues are formidable, however.[341] Transjugular intrahepatic portosystemic shunting (TIPS) has been performed safely in patients with severe VOD, although it has not been shown to improve overall survival and should be reserved for instances in which fluid retention and ascites are relatively isolated issue.[342-347]

In summary, VOD is an early complication of HSCT that occurs more frequently in patients with prior hepatic injury, intensive prior therapy, or exposure to conditioning regimens with known hepatotoxicity. The diagnosis is made on clinical criteria, including hepatomegaly, ascites, right upper quadrant pain, and increased bilirubin level; ultrasound findings can be used to further support the diagnosis. There is no standard approach to prophylaxis. Moderate VOD can be self-limiting, but multiple studies have shown a decrease in mortality from severe VOD when defibrotide therapy is employed.

IMMUNE RECONSTITUTION

The period after HCST is characterized by profound immunodeficiency, and infection complications remain an obstacle to improved HSCT outcomes. A common feature of transplant regimens, particularly for unrelated HSCT, is the use of chemotherapeutic agents and/or antibodies that effectively deplete the host of many lineages of the immune system. Myeloablative conditioning therefore results in the loss of immune cells, including T, B, and NK cells that are necessary to confer protective immunity, although some host immune populations such as resident macrophages persist after conditioning.[348] Although hematopoiesis can return within weeks of transplant, recovery of a functional immune system can take much longer, and the risk for opportunistic infection remains high for up to a year even in uncomplicated transplants. The rapidity and extent of immune reconstitution after transplantation is therefore an important determinant in outcome of HSCT.

The kinetics of recovery of the cells in the immune system after HSCT tends to follow a relatively predictable pattern. Recipients of autologous HSC rapidly recover CD3 T-cell counts within 6 to 8 weeks after transplant, whereas allogeneic HSCT recipients do not normalize their T-cell counts until 12 weeks or later. CD8+ T cells recover more rapidly than do CD4+ T cells,[349] resulting in an inversion of the normal CD4+:CD8+ T-cell ratio, although the clinical significance of this is not fully understood. NK cells reappear early after HSCT and may represent the major lymphocyte population present in the initial weeks after HSCT.[350] This timetable of immune recovery dictates the vaccination schedule of patients after HSCT, and most centers do not commence reimmunization for HSCT patients until 6 months after transplant. The rate of recovery of the immune system also has significant implications for the rate of infection, because slow recovery of immune function is associated with an increase in the cumulative incidence of infections and nonrelapse mortality.[129,207]

The recovery of the T-cell compartment in HSCT patients is from both expansion of mature T cells delivered in the donor inoculum and from de novo differentiation of T cells from early stem cell and lymphoid progenitors. During the early period after transplant, T cells with a naïve phenotype predominate in the peripheral blood, suggesting repopulation of the T cell compartment with recent thymic emigrants.[197-199] The relative numbers of recent thymic emigrants can be quantified in the peripheral blood T-cell pool by the quantitative detection of genomic DNA that is present only in thymocytes (T-cell receptor excision circle [TREC] DNA). These methods have shown that increased thymic output contributes to the expanding peripheral T-cell pool after transplant for 12 to 24 months after HSCT.[200] This thymic output occurs even in adult patients whose thymuses have presumably involuted. The rate of increase in T cells is usually much more rapid in pediatric HSCT patients, consistent with the presence of more robust thymic function.[197] The advantage of a functional thymus in immune reconstitution has been demonstrated by the marked decrease in the fraction of naïve peripheral blood T cells in a 15-year-old HSCT patient who had had a previous thymectomy relative to thymus-bearing HSCT patients.[201] The delay in recovery of the T-cell compartment is reflected in a prolonged time to manifest a normal range of T-cell diversity. Several studies have shown that it can take as long as 12 to 24 months after HSCT for a full range of T-cell receptor diversity to be present in the T-cell compartment.[198,199,202]

Mature T, B, and NK cells are present in the donor inoculum of bone marrow, peripheral blood, or UCB and can contribute to some degree of host immunity in the immediate posttransplant period. The ability of these transferred cells to provide immune protection is dependent on how immunologically "experienced" the donor is. For instance, recipients of grafts from donors who are CMV immune, that is, who have previously been infected with the virus and have mounted a protective immune response, have a lower rate of CMV disease, presumably because of transferred immunologic memory to that virus.[351] Similarly, recipients whose donors have been vaccinated with a pneumococcal vaccine respond to pneumococcal vaccines more rapidly and with higher antibody titers after transplant, again suggesting that donor immunity can be transferred to the recipient.[196] However, full immune reconstitution, with the ability to mount a protective immune response to new pathogenic challenges, is dependent on the differentiation of new immune cells from precursors in the donor graft inoculum.

Several factors influence the length of time that immunologic recovery takes. Age of BMT recipients profoundly affects the rate of immune reconstitution, with an inverse correlation between recipient age and the absolute number of T cells 1 year after HSCT.[203] The source of HSC also has a marked effect on the rate of immune reconstitution. The use of PBSC is associated with a faster rate of recovery than using HSC from bone marrow, possibly as a result of a larger cell dose.[129,204] However, increasingly intensive conditioning regimens are delaying immune recovery in autologous recipients to a degree comparable with allogeneic HSCT.[203] Although early data suggested that immune reconstitution in children after UCB HSCT is comparable to those receiving unrelated BMT,[205] subsequent studies have shown that UCB HSCT is associated with a marked delay in the recovery of T-cell numbers and function.[352-355] The presence of GVHD can significantly delay immune reconstitution both as a result of disruption of normal T-cell development and from the added immunosuppression that is required for management of the disease.[206]

GRAFT REJECTION

Primary graft rejection, defined as the failure to recover hematopoietic function of the stem cell graft by day (+) 100, is an uncommon, life-threatening event.[356] Rejection occurs after approximately 4% of UD stem cell transplants and is even less common in RD transplants.[357,358] It is an immune-mediated process that occurs because of genetic disparity between the donor and recipient.[22,359,360] Although both NK and T cells are considered mediators of graft rejection, it is characterized by the presence of recipient T cells and the gradual loss of donor cells.[361-369] The risk for graft rejection is increased in patients who are mismatched at HLA-A, HLA-B, or DRB1 loci, receive a low cell dose, have a positive crossmatch for antidonor lymphocytotoxic antibody, receive T-cell depletion as GVHD prophylaxis, have aplastic anemia, especially if previously multiply transfused, or have storage disorders or osteopetrosis.[357,358] An altered host microenvironment can also contribute to graft rejection.

Adjustments of both chemotherapeutic and radiotherapeutic components of conditioning regimens, the use of monoclonal antibodies targeting selected populations of recipient T cells, and increases in cell dose (including the use of PBSCs in addition to bone marrow) are among the interventions that have shown some promise in preventing graft rejection. Depletion of host T cells with antithymocyte globulin or the use of CD52 monoclonal antibodies to deplete residual recipient lymphocytes are commonly used options to decrease graft rejection.[370,371] A number of approaches have been exploited to overcome the increased incidence of graft failure associated with T-cell depletion. First, simply increasing the number of stem cells in the graft has been successful, implying that residual host hematopoietic elements are involved in mediating graft rejection. However, such intensification is associated with increased GVHD disease. Alternatively, approaches to increasing the number of stem cells in the graft using manipulation of Notch[372] or prostaglandin[373] pathways are being explored. Additionally, because the risk for graft failure appears to increase with more exhaustive T-cell depletion, less extensive T-cell removal from the graft with and without T-cell add-back has been attempted.[374-377] More recently attempts to reduce rejection with the use of mesenchymal stem cells have been explored.[378,379]

Therapeutic options for patients with graft rejection include second allogeneic transplant,[380] the infusion of frozen autologous stem cells, the use of hematopoietic growth factors, particularly granulocyte-macrophage colony-stimulating factor (GM-CSF), modification of the host's immunologic status, and the infusion of donor leukocytes.[256,381-386] Infusion of stem cells with or without additional conditioning can be an effective intervention for the treatment of primary graft failure.[387] It has been studied using bone marrow or PBSCs, although recently the use of unrelated UCB units[387-390] has been explored. The use of allogeneic PBSCs is appealing in the second transplant setting because PBSCs have been associated with shorter duration of the neutropenic phase and a higher neutrophil recovery rate.[381] Graft rejection is a potentially morbid, uncommon complication of HSCT with limited effective therapies.[391]

GRAFT-VERSUS-HOST DISEASE

Acute Graft-versus-Host Disease

One of the most significant barriers to successful HSCT is acute graft-versus-host disease (aGVHD). aGVHD is a syndrome caused when immunologically competent cells contained in the bone marrow or peripheral blood recognize host tissues, resulting in inflammation and tissue damage. Normally, allogeneic cells contained in simple blood transfusions are rapidly eliminated by the host immune system. However, in the setting of HSCT, the immune system of the recipient is suppressed, allowing donor immune cells to persist. The syndrome of aGVHD was first reported in 1954 by Barnes and Loutit,[6] who observed that lethally irradiated animals given allogeneic spleen cells developed skin abnormalities and diarrhea and died of a wasting illness. It became clear that for aGVHD to develop, certain criteria had to be in place, and these were summarized by Billingham in 1966[392]: (1) "the graft must contain immunologically competent cells"; (2) "the host must possess important transplantation alloantigens that are lacking in the donor graft, so that the host appears foreign to the graft and is, therefore, capable of stimulating it antigenically"; and (3) "the host itself must be incapable of mounting an effective immunological reaction against the graft, at least for sufficient time for the latter to manifest its immunological capabilities; that is, it must have the security of tenure."

In general, the greater the degree of genetic difference between donor and recipient, the higher the risk for and severity of aGVHD. The main genetic loci that determine the compatibility of donor and recipient are HLA classes I and II located on chromosome 6. Each of these loci encode polymorphic glycoproteins—major histocompatibility antigens—that are expressed on the surface of human tissues in a complex with small peptides from degraded intracellular proteins. HLA class I molecules (HLA-A, HLA-B, and HLA-C) are expressed on all nucleated cells, whereas class II antigens (HLA-DR, HLA-DQ, and HLA-DP) are primarily expressed on hematopoietic cells. T-cell receptors on the surface of T cells engage with allogeneic MHC molecules, resulting in the activation and expansion of alloantigen-specific T cells. The recognition of allogeneic MHC molecules is bidirectional: recipient T cells recognize donor antigens and can cause graft rejection; conversely, donor T cells can recognize recipient antigens and are responsible for the syndrome of aGVHD.

The mechanisms by which T cells cause GVHD include both direct effector mechanisms (i.e., killing of host cells by alloantigen-specific T cells) and also the release of inflammatory mediators that cause tissue damage. The presence of tissue damage either from immunologic events or from direct effects of conditioning can propagate the inflammatory response, triggering further immune responses, in a positive feedback loop that has been called a "cytokine storm."[393-395]

TABLE 8-1 Glucksberg Criteria for Staging and Grading of Acute Graft-Versus-Host Disease

	Stage 0	Stage 1	Stage 2	Stage 3	Stage 4
Skin	No rash	Rash <25% body surface area	25-50%	>50% generalized erythroderma	Bullae and desquamation
Intestines	<10 mL/kg/day	10-19.9 mL/kg/day	20-30 mL/kg/day	>30 mL/kg/day	Severe abdominal pain, ileus, blood or melena
Upper Gastrointestinal Tract	Severe nausea/ vomiting				
Liver	Bilirubin ≤2 mg/dL	Bilirubin 2.1-3 mg/dL	Bilirubin 3.1-6 mg/dL	Bilirubin 6.1-15 mg/dL	Bilirubin >15 mg/dL

Despite the pathologic effects of aGVHD, the allogeneic immunologic effect may also confer benefits. Patients with hematologic malignancies who develop mild-to-moderate GVHD have a decreased risk for disease relapse.[396-399] This is believed to be because graft inocula contain immunologic cells[400] that are capable of recognizing malignant cells and mediating a graft-versus-leukemia and, perhaps, a graft-versus-tumor effect,[401-403] although whether T cells that recognize tumor cells are distinct from those that simply recognize allo-MHC is not fully understood. Conversely, T-cell depletion from the marrow inocula reduces the risk for GVHD but can lead to an increased risk for both graft rejection and disease recurrence.[404]

The clinical syndrome of aGVHD develops within 100 (and usually within 60) days of allogeneic SCT. Chronic GVHD (cGVHD) is a distinctive clinical syndrome that occurs after day 100 and is discussed later. aGVHD classically involves the skin, liver, and lower gastrointestinal tract, although the degree of involvement of each organ varies. The first manifestation of aGVHD is often a rash, presenting as a maculopapular eruption, commonly involving the palms and soles, back of neck and ears at first, and later the trunk and extremities. Biopsy specimens from involved areas demonstrate epidermal basal cell vacuolization, followed by epidermal basal cell apoptotic death with lymphoid infiltration.[405] Characteristic eosinophilic bodies may be seen. The specificity of skin biopsy is not high, and it is often difficult to differentiate aGVHD from drug allergy or reaction to the conditioning regimen.[406] For this reason, skin biopsy specimens obtained early on in the transplant course are often nondiagnostic. Bullae formation with epidermal separation and necrosis is seen in advanced stages of skin GVHD.[407]

Hepatic GVHD often presents as cholestatic jaundice, which must be differentiated from other causes of liver disease frequently seen in HSCT patients, including VOD, infection, and drug toxicity.[408] Liver biopsy may be helpful because characteristic pathologic changes can be observed that aid diagnosis,[409,410] although the risk for bleeding complications is often high.

Gastrointestinal involvement presents as watery diarrhea with a “seedy” component and may progress to include crampy abdominal pain, bleeding, and even ileus.[408] By convention, stool volume is used to quantitate the severity of gut involvement. Rectal or colonic biopsy may reveal crypt cell necrosis with lymphocytic infiltration, and, with increasing severity, crypt abscess or loss and mucosal denudation.[411]

The clinical signs of aGVHD are not pathognomonic and overlap with a broad range of other complications frequently encountered during HSCT. For that reason, tissue biopsy samples of affected organs are usually obtained to confirm diagnosis by histology and exclude other infectious causes. Several groups have sought to develop better diagnostic tests for aGVHD, focusing on proteins found in the plasma that correlate with and predict the presence of GVHD; however, none has yet become integrated into clinical care.[412-415]

The severity of aGVHD is graded based on staging the involvement of individual organs and the clinical performance of the patient and then determining an overall grade for the disease. The modified Glucksberg criteria, introduced in 1974,[416] is the system historically used for assessing aGVHD (Tables 8-1 and 8-2). The International Bone Marrow Transplant Registry (IBMTR) constructed a severity index based on organ involvement alone with no need for subjective assessment of performance (Table 8-3). This has been shown to correlate well with outcome.[417] Skin, liver, and gut are staged individually for

TABLE 8-2 Glucksberg Criteria for Staging and Grading of Acute Graft-Versus-Host Disease—Overall Grade

Overall Clinical Grade	Organ System	Clinical Stage
I (mild)	Skin Liver Gastrointestinal	1-2 1 0
II (moderate)	Skin Liver Gastrointestinal	1-3 1-2 1
III (severe)	Skin Liver Gastrointestinal	2-4 2-4 2-4
IV (life threatening)*	Skin Liver Gastrointestinal	2-4 2-4 2-4

*With severe constitutional symptoms.

TABLE 8-3 International Bone Marrow Transplant Registry Severity Index for Acute Graft-Versus-Host Disease

Severity Index	Skin	Liver	Gastrointestinal	Upper Gastrointestinal
A	1	0	0	0
B	2	1-2	1-2	1
C	3	3	3	—
D	4	4	4	—

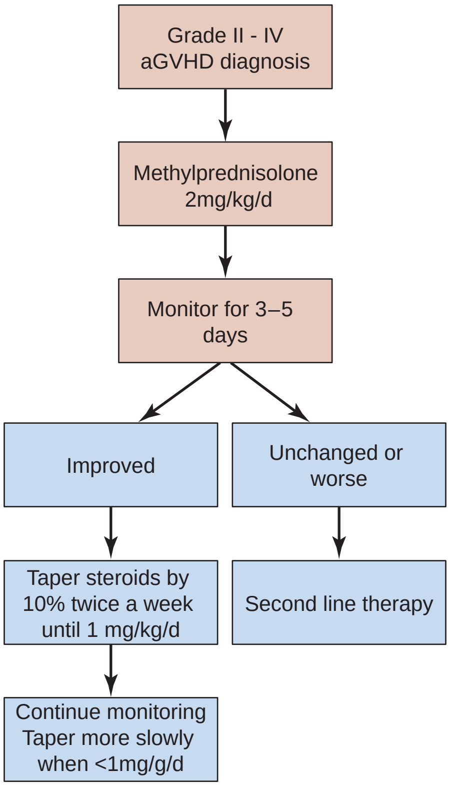
severity of involvement, after which an overall grade of GVHD is assigned.

Several risk factors have been identified for the development of aGVHD. Increasing genetic disparity between the donor and host increases the incidence and severity of GVHD[418-421] and is the most important single predictor of aGVHD. A large retrospective study of adults undergoing HSCT showed that risk factors for aGVHD grades II through IV included transplantation from UDs, mismatched RDs or UDs, the use of a TBI-based conditioning regimen, and the use of a female donor.[422] More recently, other genetic risk factors have been evaluated. The existence of polymorphisms in genes between donor and host offers a plausible mechanism to explain variations in magnitude of the inflammatory response to tissue injury and hence GVHD. Indeed, specific polymorphisms in the recipient interleukin (IL)-10 promoter region and IL-10 receptor beta gene *(IL10RB)* have been found to be associated with a lower rate of GVHD.[423] Many other candidate genes are currently being examined for similar associations.[424] Moreover, the falling cost and growing scale of genomic sequencing technologies suggest that an increasingly complex and accurate genomic prediction of GVHD risk is likely to evolve over the coming years.

Almost all patients receiving an allogeneic HSCT receive immunosuppressive therapy as prophylaxis to prevent GVHD. Prophylactic regimens originally developed in the early years of the development of HSCT included methotrexate, cyclosporine, and corticosteroids.[396,425,426] A common prophylactic regimen includes cyclosporine given intravenously at a dose of 1.5 mg/kg every 12 hours until oral administration at a dose of 6.25 mg/kg every 12 hours is tolerated. Doses are adjusted to achieve desired blood levels. Cyclosporine is continued on a tapering schedule through day 180 after transplant. Methotrexate is given at 15 mg/m^2 on day 1 and at 10 mg/m^2 on days 3, 6, and 11 after marrow infusion. Tacrolimus, which, like cyclosporine, is a calcineurin inhibitor, was tested in combination with methotrexate and found to decrease aGVHD but not overall survival.[427,428] Mycophenolate mofetil (MMF) inhibits T-cell proliferation by interfering with the purine synthetic pathway and is sometimes used instead of methotrexate to minimize toxicity (especially mucositis).[429] Sirolimus, originally identified as an antifungal agent, has potent immunosuppressive properties and, in combination with tacrolimus, is an effective prophylactic regimen.[430,431] However, the risk for VOD is increased by the use of sirolimus in some settings.[432]

Despite prophylaxis, 10% to 30% of children undergoing HSCT will develop aGVHD. For these patients, frontline therapy consists of systemic corticosteroids, typically at a dose of 2 mg/kg/day of methylprednisolone, together with calcineurin-inhibition with cyclosporine or tacrolimus (Fig. 8-1). There is no advantage to initial therapy with higher doses of corticosteroids.[433] For patients who respond to initial therapy, corticosteroids are tapered by 10% every 3 to 5 days and then more slowly after doses are decreased to less than 1 mg/kg/day. However, because approximately 35% of patients do not improve with initial corticosteroid therapy,[434] several other agents have been used in combination with corticosteroids to increase the efficacy of frontline treatment.[435] A recent, randomized phase II study in adults undergoing HSCT demonstrated that the addition of MMF showed improved efficacy compared with etanercept (which inhibits tumor necrosis factor [TNF]), denileukin (which targets cells expressing the IL-2 receptor), or pentostatin (which inhibits purine synthesis).[436]

If aGVHD progresses or fails to improve after 5 to 7 days of initial corticosteroid therapy, it is considered to be corticosteroid refractory and additional immunosuppressive therapies are added. A variety of other pharmacologic agents have been tried, including methotrexate, MMF, IL-2 receptor–targeting agents, etanercept, infliximab, antithymocyte globulin, and sirolimus.[435] However, none is clearly superior; and, instead, most clinicians select second-line aGVHD therapy based on the effects of previous treatment regimens used in a given patient



Grade II - IV aGVHD diagnosis
Methylprednisolone 2mg/kg/d
Monitor for 3–5 days
Improved
Unchanged or worse
Taper steroids by 10% twice a week until 1 mg/kg/d
Second line therapy
Continue monitoring Taper more slowly when <1mg/g/d

TABLE 8-4 Comparison of Acute and Chronic Graft-Versus-Host Disease

	Acute GVHD	**Chronic GVHD**
Onset Day	7-60 (up to 100)	Day >100 (may be seen from day 60 on)
Manifestations		
Skin	Erythematous rash	Sclerodermatous changes
Gastrointestinal	Secretory diarrhea	Dry mouth; sicca syndrome
Liver	Hepatitis/cholestasis	Cholestasis/cirrhosis
Other	Fever	Pulmonary dysfunction, alopecia, thrombocytopenia, xerostomia

and on the spectrum of toxicities associated with each agent.[435]

Chronic Graft-Versus-Host Disease

GVHD was initially characterized as occurring in two phases: aGVHD generally presented within the first 100 days after transplant, whereas cGVHD occurred after day 100 (Table 8-4). cGVHD, defined by both clinical and histopathologic criteria, can present as early as day 50 to 60 days after marrow infusion.[437] The pathogenesis of cGVHD is not completely elucidated. It is believed to involve donor T-cell recognition of minor histocompatibility antigens or loss of peripheral T-cell tolerance, leading to symptoms that are very similar to those present in autoimmune disorders. The morbidity and mortality of cGVHD is most severe in patients who have progressive disease after aGVHD and tends to be less severe in those in whom it occurs de novo.[438] Risk factors for development of cGVHD include HLA disparity between donor and host, prior aGVHD, increasing patient age, and use of a TBI-based conditioning regimen. Age is also a risk factor: patient age older than 15 years or donor age older than 5 years is associated with significantly increased risk.[439] In addition, the use of adult female donors for male recipients increases the likelihood of cGVHD, likely related to donor antibody responses to antigens coded for by genes on the recipient Y chromosome.[440] The impact of pediatric female donors on the incidence of cGVHD has not been evaluated.

cGVHD is a disease with a constellation of clinical and pathologic features. The syndrome resembles autoimmune systemic collagen vascular diseases with protean manifestations potentially involving almost every organ (Table 8-5). Pathologic changes in the skin result from epithelial cell damage characterized by basal cell degeneration and necrosis, and, later, epidermal atrophy and dermal fibrosis.[441] Skin involvement may present as lichen planus, areas of local erythema, and areas of hyperpigmentation or hypopigmentation. The skin may be dry, freckled, or ulcerated; and findings are aggravated by exposure to sunlight. Sclerodermatous changes may evolve to flexion contractures that can greatly impair function and may be helped by surgical release procedures. Hair follicles can be involved with resulting partial or total alopecia. Ocular abnormalities are common, and patients present with sicca syndrome, including dry eyes and photophobia; decreased tearing is quantitated by a Schirmer test. Dry mouth is a common presenting complaint of oral GVHD, and decreased saliva production predisposes to caries. Tongue depapillation or scalloping

TABLE 8-5 Clinicopathologic Features of Chronic Graft-Versus-Host Disease

Organ System	**Symptoms and Signs**	**Biopsy Findings**
Systemic	Recurrent infections with immunodeficiency	
Skin	Lichen planus, scleroderma, hyperpigmentation or hypopigmentation, dry scale, ulcerated, erythema, freckling Flexion contractures	Epithelial cell damage, basal cell degeneration and necrosis, epidermal atrophy and dermal fibrosis
Hair	Alopecia	
Mouth	Sicca syndrome, depapillation of tongue with variegations, scalloping of lateral margins	Lichenoid changes with mononuclear infiltrates, epithelial cell necrosis, salivary gland inflammation, lymphocyte infiltration, fibrosis
Joints	Decreased range of motion, diffuse myositis/tendonitis	
Eyes	Decreased tearing, injected sclerae, conjunctivae	
Liver	Increased alkaline phosphatase > aminotransferases and bilirubin Cholestasis, cirrhosis	Focal portal inflammation with bile ductile obliteration, chronic aggressive hepatitis, bridging necrosis, cirrhosis
Gastrointestinal	Failure to thrive (children), weight loss (adults) Esophageal strictures, malabsorption, chronic diarrhea	Crypt destruction, single-cell dropout, fibrosis of lamina propria
Lung	Cough, dyspnea, wheezing Bronchiolitis obliterans, chronic rales, pneumothorax	
Hematology	Refractory thrombocytopenia, eosinophilia, Howell-Jolly bodies	

of the lateral margins of the tongue can be seen. The tongue, buccal mucosa, and gums may have lichen planuslike lesions, which must be differentiated from oral candidiasis. A biopsy specimen typically shows lichenoid changes with mononuclear infiltrates, epithelial cell necrosis, and salivary gland inflammation, lymphocytic infiltrate, and fibrosis. Involvement of the liver with cGVHD is manifest by obstructive jaundice, which may progress, if untreated, to bridging necrosis and cirrhosis. Gastrointestinal signs include inanition with progressive weight loss, chronic malabsorption, diarrhea, anorexia, nausea, and vomiting. Biopsy demonstrates single cell apoptosis with crypt destruction and may show fibrosis of the lamina propria. Early cGVHD may present as diffuse myositis and tendonitis. Progressive joint involvement, which may result from the myositis and tendonitis or simply from overlying skin fibrosis, results in decreased range of motion and flexion contractures. Perhaps the most debilitating effect of cGVHD occurs with pulmonary involvement, manifest as obstructive lung disease progressing to bronchiolitis obliterans. Persistent immunodeficiency with profoundly depressed B- and T-cell responses predisposes to recurrent and severe infections. Patients may have reduced IgG2 and IgG4, decreased mucosal IgA, diminished delayed-type hypersensitivity, and functional asplenia. They are susceptible to opportunistic infections with encapsulated organisms (primarily pneumococcus), *P. jirovecii,* varicella-zoster, and herpes simplex and may have a variety of chronic infections, including sinusitis, bronchitis, and conjunctivitis.

Staging of cGVHD is based on degree of organ involvement (Box 8-2). Limited cGVHD has localized skin involvement with or without hepatic dysfunction. All other manifestations of cGVHD are classified as extensive cGVHD.[441] Limited cGVHD may resolve spontaneously without specific therapy, and these patients have a favorable outcome.[438] Patients with lichenoid skin changes, progressive presentation of cGVHD, and hyperbilirubinemia have a worse prognosis.[442,443] Recent work has focused on developing a more detailed comprehensive scale to measure symptoms of cGVHD so that response to therapy can be more clearly assessed.[444]

It is essential that patients with cGVHD are managed by a multidisciplinary team with expertise in this complicated and often frustrating condition. Corticosteroids are usually the first approach to therapy, and a regimen of alternating-day cyclosporine and prednisone was shown to be effective in more than half of patients and to have an acceptable toxicity profile.[445,446] There is no standard approach for patients who are refractory to initial therapy or whose disease flares during taper of immunosuppression.[447] A number of other therapies are being tested, including high-dose pulse corticosteroids,[448] extracorporeal photopheresis,[449-452] daclizumab (a humanized IL-2 receptor antagonist),[453] mycophenolic acid,[454,455] rapamycin,[456,457] rituximab,[458-461] imatinib,[462] and pentostatin.[463] Recent studies have also examined the use of IL-2 in the treatment of GVHD, which may work by selectively expanding regulatory T cells.[464]

All of the therapeutic options significantly impact immune function, and most fatalities occur from infectious complications versus specific organ toxicity from cGVHD. Meticulous and preemptive management of the complications associated with cGVHD and its therapy is a crucial component of care. Recommendations for patient education, prophylactic interventions, and follow-up are extensively outlined in the National Institutes of Health Ancillary Therapy and Supportive Care Working Group document.[465]

Box 8-2 **Staging of Chronic Graft-Versus-Host Disease**

  Eye involvement: Schirmer test (<5 mm wetting), *or*
  Involvement of minor salivary glands or oral mucosa demonstrated by buccal biopsy, *or*
  Involvement of any other target organ

ORGAN TOXICITY ASSOCIATED WITH HEMATOPOIETIC STEM CELL TRANSPLANTATION

Ophthalmologic Complications

A number of different ophthalmologic complications can occur as sequelae of HSCT.[466-468] Decreased lacrimation secondary to cGVHD may contribute to ocular sicca syndrome and the related complications of photophobia, punctate keratopathy, scar formation, and corneal perforation. Dry eye syndrome can occur independent of GVHD and is attributed to immunosuppression and conditioning with TBI.[469-471] Therapy includes topical or systemic immunosuppression, lubrication, artificial tears, and lacrimal duct (punctual) plugging, which can be useful even in young children.[469-471] Fluid-ventilated scleral lenses have been used to treat adolescents and adults with sicca syndrome and have decreased corneal abrasions and improved vision.[472] Patients remain at risk for ocular infections, particularly with herpes simplex viruses. Cyclosporine use is associated with a number of eye complaints, including a well-described syndrome of headache, hypertension, seizures, visual impairment, or any combination of these symptoms, as well as temporary blindness (see "Neurologic Complications" for a detailed description).[178,473,474] In addition, transplant-related retinopathy can be manifested as optic disc edema, either asymptomatic or accompanied by visual blurring, in patients taking cyclosporine. Ischemic fundal lesions, detected as cotton-wool spots and, in some patients, as optic disc edema, have been reported in patients treated with both TBI and cyclosporine and were not observed in patients who did not have concordance for these risk factors.[475,476] Lesions appeared 3 to 6 months after SCT, with complaints of decreased visual acuity or other visual disturbances. Most patients discontinued cyclosporine, and half were treated with systemic corticosteroids. The majority recovered visual acuity, and their ischemic lesions resolved over time, but little further information is available about the course or long-term prognosis of this complication.

Retinal hemorrhages are relatively common after transplantation and in one study were found in 12% of children undergoing scheduled ophthalmologic examination after transplant.[467] In this study, the hemorrhages were located intraretinally, did not threaten vision, and developed in the acute transplant period in the setting of thrombocytopenia. In all cases the hemorrhages ultimately resolved when the platelet count recovered.

Occlusive microvascular retinopathy has also been described after autologous SCT in patients receiving high-dose cytarabine and TBI, thus suggesting that particular high-dose chemotherapy regimens may predispose to vascular injury at otherwise safe radiation doses.[477] Other infrequent complications of transplantation include chorioretinal lesions, vitritis, increased ocular pressure, and retinal hemorrhages.

Cataracts are a common complication of HSCT. Radiation is a well-described predisposing factor. GVHD and treatment with corticosteroids are inconsistent risk factors across studies.[478-481] Although historically the incidence was as high as 80% in patients receiving single-dose TBI, patients receiving fractionated TBI or chemotherapy-only regimens still have a 20% to 50% incidence of cataracts 5 to 6 years after transplantation.[482,483] The relative risk for cataracts and the need for subsequent cataract surgery may also be related to previous therapy or to glucocorticoid use for prophylaxis or management of GVHD.

Overall, reports of large pediatric populations have shown that some type of ophthalmologic abnormality occurs in up to 50% of patients, although visual function remains excellent in virtually all patients.[484,485] Thus yearly examination by an ophthalmologist is essential, including a Schirmer test to rule out xerophthalmia and a thorough retinal evaluation.

Dental Complications

Disturbances in dental development have been described in children conditioned with TBI, particularly if HSCT took place before 6 years of age.[486,487] Characteristic findings include short dental roots, absence of root development, and microdontia. A review of 52 pediatric patients younger than 10 years at HSCT found that all patients had disturbances in dental root growth, with the most pronounced changes occurring in those 3 to 5 years old at the time of transplantation.[488] Subsequent decreased alveolar bone growth may lead to further compromise of dental development.

Oral sicca syndrome (occurring as a complication of either TBI or cGVHD, or both) may result in significant morbidity, including chronic oral mucosal injury, poor oral hygiene, and subsequent dental decay.[489-491] Patients report frequent thirst, altered taste, difficulty eating and swallowing, and oral sensitivity.[489] The salivary glands are a common site of cGVHD and results in both quantitative and qualitative deficiencies of the major and minor salivary glands resulting in decreased salivary flow.[489,492,493] Decreased salivary production alters the biochemical and immunologic composition of the saliva and can contribute to the development of caries.[489,492,493] The primary treatment of sicca syndrome includes sialogogue therapy—stimulants such as sugar-free gum or prescription medications. Patients with oral sensitivity should avoid foods that cause discomfort and heavily flavored toothpastes or alcohol-based mouthwashes.[494]

Children with oral GVHD and certain underlying diseases such as Fanconi anemia are at heighted risk for oral cancers.[495-498] These patients should receive routine evaluation by an oral medicine specialist comfortable with oral cancer screening. The effects of prophylactic interventions are not well reported, but routine oral hygiene including brushing and flossing and twice-yearly evaluation by a dentist knowledgeable about potential HSCT-related issues is recommended.[494]

Pulmonary Complications

Acute and late noninfectious pulmonary complications are common and occur in as many as 50% of pediatric HSCT patients.[499] Pulmonary illness complicates both autologous and allogeneic HSCT; however, these toxicities are more common after allogeneic transplant.[500] Patients with pulmonary complications have a higher overall mortality compared with patients who do not develop pulmonary complications.[500,500a,501] The spectrum of noninfectious lung disease includes idiopathic pneumonia syndrome (IPS), diffuse alveolar hemorrhage (DAH), bronchiolitis obliterans syndrome (BOS), bronchiolitis obliterans organizing pneumonia (BOOP), and periengraftment respiratory distress syndrome (PERDS).

IPS is a potentially fatal acute complication of transplantation that is characterized by respiratory compromise, hypoxia, and diffuse radiographic change in the absence of an identifiable infectious cause. In 2010 the American Thoracic Society updated the definition of IPS as an idiopathic syndrome of pneumopathy after HSCT with evidence of widespread alveolar injury and in which infectious causes and cardiac dysfunction, acute renal failure, or iatrogenic fluid overload have been excluded.[502] They further classified it into specific entities based in large part on the primary anatomic sites of inflammation and dysfunction. Subtypes of IPS include acute interstitial pneumonitis, DAH, delayed pulmonary toxicity syndrome (chemotherapy induced), and PERDS.[499,502] IPS typically presents between 6 to 7 weeks after allogeneic HSCT, but studies have reported cases presenting earlier and later.[503-505] Risk factors for IPS allogeneic HSCT include allogeneic transplant, full-intensity conditioning, the use of TBI in the conditioning regimen, the presence of aGVHD, older recipient age, and an underlying diagnosis of acute leukemia or MDS.[502,505-509] The treatment of IPS includes supportive respiratory care with oxygen, diuretics, and often mechanical ventilation. The mainstay of medical therapy is systemic corticosteroids. Recently the soluble TNF-binding agent etanercept has shown promise if started early in the course of illness along with a corticosteroid.[504,510,511] Despite advances in ventilatory management, supportive care, and medical therapy the mortality rate for IPS remains high. It is reported to be as high as 80% for all patients and 95% for ventilated patients.[499,502,505,507,511] It should be noted that most reports of IPS include adult patients and it is likely that mortality rates are lower when children are considered independently.

DAH is an acute complication that typically develops in the periengraftment period in both allogeneic and autologous transplant patients.[502,512-516] It is characterized by shortness of breath, cough, and hypoxemia, often with fever. The diagnosis of DAH is based on progressively bloodier return of bronchoalveolar fluid in the appropriate clinical setting. Frank hemoptysis is rare.[502,512] Chest imaging demonstrates bilateral, diffuse infiltrates with potential areas of consolidation typically in the central lung.[517] Risk factors for DAH include older age, transplantation for metabolic disease or solid tumor, severe mucositis, and renal insufficiency.[503,512,517-520] DAH is treated with respiratory supportive care, transfusional support, and high-dose systemic corticosteroids (2 mg/kg/day to 1 g/m^2/day) with slow taper.[513,514,518,521] Even in the setting of rapid and complete treatment the mortality from DAH ranges from 60% to 100%, with death usually the result of multiorgan failure.[513,514,518,521]

PERDS is a subset of IPS that occurs within 5 days of engraftment and is the respiratory component of clinical engraftment syndrome. Other components of engraftment syndrome include rash, fever, capillary leak, and diarrhea. Diagnostic criteria for PERDs include fever, hypoxia, and/or pulmonary infiltrates identified by imaging that occurs within 5 days of engraftment without evidence of infection or pulmonary dysfunction.[522] There can be overlap with DAH, and approximately 30% of patients with PERDS have DAH.[522,523] PERDS that occurs independently of DAH responds well to therapy with systemic corticosteroids (1 mg/kg/day), and death is uncommon.[502,522,523]

BOOP (also called cryptogenic organizing pneumonia) presents as dry cough, fever, and dyspnea and is pathologically characterized by presence of granulation tissue within the alveolar ducts and alveoli.[499,523,525,526] BOOP can present in the immediate posttransplant course or as late as 2 years after HSCT.[523,527] Pulmonary function testing shows a restrictive defect, decreased diffusing capacity for carbon monoxide (DLCO), and hypoxemia.[523,527] Chest imaging demonstrates patchy airspace consolidation and ground-glass and nodular opacities in a bilateral or unilateral pattern.[528,529] Although clinical findings may support the diagnosis of BOOP, the diagnostic standard requires tissue either obtained by transbronchial or surgical biopsy.[523] Unlike BOS, described next, BOOP responds well to systemic corticosteroids and most patients are long-term survivors.

Obstructive lung disease has been reported in up to 20% of children after allogeneic HSCT, which is similar to the incidence in adult patients. BOS is a noninfectious, potentially life-threatening complication of HSCT. It is a pathologic process that leads to the obstruction and eventual obliteration of the small airways[530] and is characterized by chronic airflow obstruction that is unresponsive to bronchodilator therapy.[531] The etiology of BOS is not fully understood. It is believed that immunomodulatory and inflammatory mechanisms play roles in its development.[532] This is supported by an association between BOS and cGVHD.[533] BOS has been associated most firmly with cGVHD, although associations with viral infections prior to day +100 and gastroesophageal reflux have also been reported.[531,533-535] Pulmonary function tests reveal an obstructive pattern with reduction in the forced expiratory volume in 1 second (FEV$_1$) and ratio of FEV$_1$ to forced vital capacity (FVC). High-resolution computed tomographic examinations with inspiratory and expiratory views have been shown to be sensitive and specific indicators of BOS in HSCT patients.[536-538] Characteristic findings include air trapping, a mosaic pattern of lung attenuation, and bronchiectasis.[522,536-539] BOS is traditionally treated with immunosuppressive agents, with corticosteroids being first-line treatment, although corticosteroid-resistant disease is common and portends a poor prognosis. Azithromycin has been shown to be a useful adjunct to customary immunosuppression in some patients.[540,541] Published mortality rates for BOS after HSCT range between 21% and 100%.[531,542,543] The prognosis after developing BOS depends in part on the tempo of the disease and the response to first-line therapy.[531,544] Rapid onset BOS and lack of response to first-line immunosuppression are poor prognostic indicators.[544]

Restrictive and diffusion abnormalities have been reported in pediatric patients after SCT.[545,546] These findings improved over time but do not normalize.[545] Risk factors for restrictive lung disease include sclerodermatous type GVHD, single-fraction TBI, abnormal chest wall growth due to radiation, and certain chemotherapeutic agents.[546-551] Treatment depends on the underlying cause of the pulmonary disease. Because restrictive changes can be asymptomatic, assessment of the frequency of this complication depends on the intensity of post-SCT follow-up. Pulmonary compromise can influence the morbidity and mortality of survivors of HSCT. When developmentally appropriate, all HSCT recipients should have pulmonary function testing at 1-year post transplant. Providers should have a low threshold for screening patients who have risk factors for pulmonary complications earlier and more frequently. High-resolution chest tomography should be considered in high-risk patients who are unable to successfully complete pulmonary function testing.

Hematologic Complications

Patients who undergo ABO-incompatible allogeneic HSCT are at risk for immune hemolytic anemias. In the setting of major ABO incompatibility (e.g., recipient O and donor A or B), preexisting patient isohemagglutinins can cause lysis of donor red cells. This can potentially cause an acute hemolytic reaction during stem cell infusion, and thus anti-A or anti-B isoagglutinins must be removed from the patient before infusion via pheresis or the stem cell product must undergo red cell depletion. Although the acute issues surrounding transplantation in the setting of major ABO incompatibility are easily managed and not associated with any impact on outcome, pure red cell aplasia may develop in up to a fourth of at-risk patients in the months after HSCT.[552] This occurs when long-lived patient lymphocytes continue to produce antibodies capable of destroying red cell precursors in the graft. Patients who are type O and donors who are type A are at greatest risk, presumably related to the level of isohemagglutinin titers.[553] A relationship of red cell aplasia to posttransplant immunosuppression with cyclosporine alone has been suggested because calcineurin inhibitors permit longer persistence of patient B cells than methotrexate does.[554] Some cases of aplasia will resolve spontaneously over time; plasma exchange with donor-type plasma replacement has also been used, and, more recently, rituximab, a chimeric anti–B-cell antibody, has been used with success.[555] Minor ABO incompatibility (e.g., patient A, donor O) is managed by plasma depletion of the graft before infusion. This situation can also lead to low-level hemolysis in the first months after HSCT as newly formed B lymphocytes produce isohemagglutinins targeting residual patient red cells. Occasionally, in the months to years after transplantation, autoimmune hemolytic anemia, autoimmune thrombocytopenia, or autoimmune neutropenia develops as a result of immune dysregulation after HSCT. Corticosteroids and intravenous immune globulin are usually the first therapeutic intervention, but rituximab has been used in this setting as well.[556,557]

Renal Complications

Chronic kidney disease (CKD) is a common complication in long-term survivors of HSCT, occurring in 20% to 60% of adult transplant recipients and as many as 62% of pediatric HSCT survivors.[558,559,560,561] The incidence of chronic nephropathy is probably underestimated. Up to 25% of adults undergoing allogeneic HSCT were affected at 10 years; posttransplant hypertension was the most significant predictor of CKD.[562] Assessment of renal function by determination of the glomerular filtration rate revealed renal impairment in 41% of pediatric patients 1 year after HSCT and in 11% at 7 years, with exposure to TBI being the most significant risk factor.[563] HSCT survivors with CKD can progress to end-stage renal disease (ESRD). Survivors of HCT who develop ESRD have decreased survival compared with other patients with ESRD who did not did not undergo HCT.[564] Factors that contribute to CKD and ESRD may begin during the acute transplant period.

The long-term impact of transplantation on renal function in pediatric patients is not known, but given the natural decline in renal function with age, monitoring function over time should be part of routine care for survivors of pediatric HSCT.

It has been demonstrated that the presence of proteinuria, a marker of nephropathy, at transplant day 100 increases the risk for nonrelapse mortality by as great as sixfold by 1 year after HSCT.[558] Albuminuria is considered to be a marker of endothelial dysfunction and/or inflammation.[565] It is postulated that albuminuria reflects a systemic, generalized endothelial injury and is associated with increased risk for nonrelapse mortality in the first transplant year. Albuminuria has been identified as a risk factor for cardiovascular and noncardiovascular mortality in the general and other patient populations.[566-570] However, little is known about risk factors for CKD progression or why CKD and proteinuria increase nonrelapse mortality in the HSCT patient population. As this is explored in prospective studies it is suggested that children with albuminuria are considered for referral to a nephrologist experienced with posttransplant care.

HSCT-associated thrombotic microangiopathy including hemolytic uremic syndrome and thrombotic thrombocytopenic purpura are complications that occur in 25% to 35% of HSCT.[571] These entities are characterized by vascular endothelial cell injury resulting in microangiopathic hemolytic anemia, thrombocytopenia, fibrin deposition in the microcirculation, and tissue damage.[571] Hemolytic uremic syndrome may develop at a median of 5 months after HSCT.[572,573] This disorder is generally manifested as moderate hemolysis and renal dysfunction, although some patients have more aggressive findings consisting of severe hypertension and seizures. Factors implicated in the development of this syndrome include exposure to radiation and use of calcineurin inhibitors.[574,575] The majority of reported cases appear to resolve spontaneously over time, although modest persistent anemia and decrements in renal function have been described. Thrombotic thrombocytopenic purpura is rare in pediatric patients and may result from more pervasive endothelial damage than seen in hemolytic uremic syndrome. It usually occurs in the first months after HSCT and can have associated fever, bloody diarrhea, and neurologic symptoms. Unlike classic thrombotic thrombocytopenic purpura, HSCT-associated thrombotic thrombocytopenic purpura is not accompanied by deficient von Willebrand multimer proteolysis and plasma exchange therapy is generally unsuccessful.[576]

Neurologic Complications

Patients undergoing HSCT may experience a variety of neurologic complications either directly related to treatment or the underlying diagnosis, as a consequence of immunosuppression, or as a result of medications used in supportive care.

Neurologic side effects are well described when cyclosporine and tacrolimus are used for GVHD prophylaxis.[577,578] Commonly described side effects include essential tremor and paresthesias, both of which typically resolve when the dose is decreased or formulation changed.[577] Seizures, visual disturbances, and encephalopathy are more significant but rarer neurologic complications.[579] Posterior leukoencephalopathy is a syndrome associated with seizure, transient blindness, visual hallucinations, and motor deficits.[578,580] It has been postulated that both seizures and acute visual loss arise from vasogenic edema accompanying cyclosporine-associated hypertension. Hypomagnesemia and elevated calcineurin inhibitor levels can be aggravating factors. These changes affect white matter, most commonly in the occipital area, and are accompanied by characteristic radiologic findings on magnetic resonance imaging (MRI).[581,582] In general, symptoms abate rapidly on discontinuation or decreases in the dose of cyclosporine.[583] A rare, severe complication of cyclosporine is manifested by parkinsonian motor features, ataxia, and/or quadriparesis.[577,584] These changes may improve with discontinuation of the medication or may be permanent. There are fewer neurologic side effects reported for corticosteroids. However, mood swings or even frank psychosis accompanying corticosteroid therapy are well described.[585]

Acyclovir is used for both prophylaxis and treatment of infection with herpes simplex viruses. Confusion, tremors, delusion, and psychosis have been associated with this drug.[586] Similarly, mental status changes, paresthesias, and, uncommonly, seizures have been reported with the antiviral agents ganciclovir and foscarnet.[587,588] Impaired renal function, often seen in HSCT patients, may potentiate the occurrence of these symptoms.

Cerebrovascular accidents, including cerebral hemorrhage, may also be observed after SCT and are usually associated with refractory thrombocytopenia. Large intracranial hemorrhages are generally fatal; patients with isolated subdural hematomas typically do well.[589,590]

Central nervous system (CNS) infectious complications related to immunosuppression, cGVHD, or both can arise after HSCT. The greatest risk for CNS infection is between the second and sixth months after transplantation.[577] The manifestations of CNS infection can differ from those in an immunocompetent patient in that localizing signs and symptoms may be less dramatic. Autopsy series demonstrate that up to 15% of necropsy patients harbor CNS infections, often clinically unsuspected.[591,592] *Aspergillus* species and *Toxoplasma gondii* are the most common organisms found.[593] Bacterial meningitis or encephalitis/meningoencephalitis caused by a variety of viruses, including CMV, herpes simplex types 1 and 6, adenovirus, and varicella-zoster, can also occur.[594] Routine antiviral prophylaxis and CMV screening and treatment of reactivation have reduced the incidence of viral CNS infections.[595,596] Opportunistic CNS infections in HSCT recipients are often fatal, and a high level of suspicion is warranted in patients with even minimal neurologic symptoms.[593]

Leukoencephalopathy is a poorly understood sequela of HSCT that is manifested as progressive neurologic deterioration in the months after transplantation. Clinical findings include lethargy, slurred speech, ataxia, seizures, decreased sensorium, dysphagia, spasticity, or even decerebrate posturing. Consistent white matter changes are found on MRI. In a series of 415 patients from Seattle, leukoencephalopathy was observed in 7% of patients, but only in those who had received CNS radiation, intrathecal therapy, or both before HSCT in conjunction with intrathecal methotrexate after HSCT.[597] More recently, a 4% incidence of irreversible leukoencephalopathy was reported in children receiving cyclosporine; a third of the patients died during the period of neurologic decline.[598] Cyclosporine levels were usually therapeutic in the affected patients, and it remains unclear what the risk factors are for this rare but devastating complication.

CNS involvement in GVHD is highly debated.[599] There are case reports of potential clinical and pathologic cases of possible CNS GVHD involvement in the literature.[577,600-603] The clinical presentation is variable and can include seizure, encephalopathy, and focal neurologic dysfunction.[577,600] MRI may show infarction, leukoencephalopathy, and/or hemorrhages.[604] Definitive diagnosis requires pathologic findings in the brain similar to GVHD changes in systemic organs.[577] Systemic immunosuppression is the mainstay of treatment.

The effects of different conditioning regimens on neuropsychologic functioning have been incompletely investigated. In particular, analysis of very young patients is limited. Nonetheless, it is clear that a significant proportion of young children, including those younger than age 2 years, can undergo HSCT with chemotherapy and TBI and subsequently have normal neurologic development, perform well in areas such as sensorimotor and cognitive functioning, and have no decrement in academic achievement.[605-607] Age at HSCT appears to be the most consistent risk factor predicting subsequent cognitive decline.[607,608]

Endocrine Disorders

Much of the endocrine dysfunction after HSCT results from irradiation and is attenuated in both incidence and severity when radiation is fractionated or when non–radiation-containing conditioning regimens are used. Thyroid dysfunction is one of the most frequent late complications of HSCT reported in between 0% and 52% of transplant survivors.[609-612] After fractionated TBI, the incidence of compensated hypothyroidism ranges from 13% to 39% and that of overt hypothyroidism is around 15%, with diagnosis occurring at a median of 4 years after HSCT.[613-615] Patients treated with BU-based regimens have a lower, but still significant incidence of thyroid complications: 20% compensated and 9% overt hypothyroidism.[616,617] Undergoing transplant when younger than age 10 years is a risk factor for thyroid dysfunction, suggesting that the developing thyroid has increased susceptibility to toxicity.[609,618] Given that the incidence of thyroid dysfunction increases over time, clinical suspicion and yearly monitoring of thyroid function tests are an important part of long-term care for these patients.

Growth disturbance is a late effect specific to pediatric transplantation and is a common problem. However, the incidence of growth disturbance is unclear because multiple different definitions are used in the literature with published incidences between 20% and 82%.[619-621] Linear growth after HSCT is affected by many factors: nutritional status, thyroid and/or growth hormone disturbance, previous therapy, particularly corticosteroids or cranial or spinal radiation therapy, age at transplantation, conditioning regimen, and development of cGVHD with associated long-term corticosteroid exposure. Growth is most disrupted in children who underwent cranial irradiation before HSCT, followed by a TBI-based conditioning regimen due to disturbance of the pituitary axis.[622] This group of children is also at greatest risk for growth hormone (GH) deficiency. If the GH levels are deficient, GH replacement can have a positive impact on final height, particularly in children younger than 10 years at the time of HSCT. Therapy is not associated with an increase in relapse; however, a higher incidence of osteochondromas/exostosis was seen in GH-treated patients.[623] Nonetheless, many children do not demonstrate GH deficiency, and the role of exogenous hormone in these children or in children older than 10 at the time of diagnosis of GH deficiency is not clear.[624,625] Overall, the mean loss of height appears to be approximately 6 cm, as predicted by both genetic height and height at transplantation.[615] Still, nearly 80% of those undergoing HSCT in childhood will achieve a height that is within 2 standard deviations of adult norms.[626]

Gonadal failure after HSCT is common; predictors include previous gonadotoxic therapy and the preparative regimen used for transplantation. For example, children with aplastic anemia who receive CY as their only cytotoxic agent almost always progress normally through puberty, whereas those receiving a BU- or TBI-based ablative regimen are very likely to have delayed development.[625] Thus these children must be carefully monitored by a pediatric endocrinologist as they approach adolescence so that hormone replacement can be appropriately administered. Females who are postpubertal at the time of HSCT also need to be evaluated for hormone replacement therapy. In addition, they are at risk for gynecologic complications, including reduced uterine size, decreased vaginal and cervical size, atrophic vulvovaginitis, introital stenosis, and loss of pubic hair.[627] No comparable data regarding these complications exist for those prepubertal at the time of HSCT. In postpubertal males, HSCT with or without radiation-based conditioning often results in azoospermia, and sperm banking should be offered to all patients with sufficient spermatogenesis.[628] Significant Leydig cell damage resulting in decreased testosterone and decreased testicular volume is less common.[629] In both sexes, spontaneous recovery of gonadal function has occurred years after HSCT. Fertility resulting in liveborn infants has been reported for both male and female SCT patients, particularly after conditioning with CY alone.[630,631] Successful pregnancies are much less common after BU- and TBI-based regimens, and there is an increased risk for spontaneous abortion, preterm labor, and delivery of low- or very-low-birth-weight infants. There does not, however, appear to be an increased incidence of congenital anomalies in the offspring.[629] Concern regarding fertility is one of the major issues for HSCT survivors up to a decade after transplantation.[632]

Bone Problems

The most prominent bony complications after HSCT are decreased bone mineral density (BMD) and osteonecrosis. HCT may result in decreased bone mineral density, which may lead to osteopenia and osteoporosis with associated increased risk for fracture, loss of independence, immobility, chronic pain, and an overall decreased quality of life. Because many patients are asymptomatic, the incidence of osteopenia/osteoporosis in children and the impact on future bone health are not well understood. Small series of pediatric patients indicate that up to 50% of survivors of childhood allogeneic HSCT will have abnormal BMD and thus have an excess risk for fractures and other skeletal complications as they age.[633-635] The Bone Marrow Transplant Survivor Study reported a prevalence of osteoporosis of 9% in long-term survivors (median age 36.5 years) of HSCT for acute leukemia.[636] This was significantly higher than the prevalence of 2.2% in the siblings of the transplant patients. Allogeneic transplant and female sex was associated with increased risk for osteoporosis. There are few reports of posttransplant BMD changes in children, and most are from small, single-center, and retrospective studies.[635,637-639] The single prospective analysis of 29 children after HSCT demonstrated that most bone mineral loss occurs within the first 6 months after transplantation.[638] Studies of adult HSCT patients demonstrate that posttransplant bone turnover is characterized by increased resorption and decreased bone formation and that alteration in BMD is preceded by changes in markers of bone turnover such as serum osteocalcin, serum alkaline phosphatase, and urine amino-terminal telopeptide (N-telopeptide, NTX). It is not known if these patterns are the same in children, and a detailed understanding of how bone mineral status changes during and after HSCT is lacking.

Children are at risk for decreased BMD after HSCT due to factors related to their diagnosis and treatment including the underlying disease, pre-HSCT therapy (especially with corticosteroids), conditioning chemotherapy and TBI, osteotoxic medications, and presence of and treatment for GVHD.[640] Studies of adult patients have shown that the chemotherapy and radiation used in HSCT conditioning can mediate skeletal toxicity in two ways. First, damage can occur through direct insult to osteoprogenitor cells.[641-643] Second, cytokine release during the initial weeks after HSCT can activate osteoclasts resulting in increased bone resorption.[644,645] The RANK/RANKL/OPG pathway is believed to be the primary mediator of osteoclastic resorption after conditioning.[643,646] Receptor activator of the nuclear factor-κB ligand (RANKL) and RANKL/OPG (osteoprotegerin) ratio increase after transplant-stimulating osteoclastogenesis.[643,646]

Osteonecrosis or avascular necrosis, the death of a segment of bone, is a potentially debilitating manifestation of bone disruption and can result in significant pain or fractures. Corticosteroid use and the presence of cGVHD appear to be the major risk factors, and children older than age 10 years appear to be at more risk than younger children.[647,648] Joints of the lower limb, particularly the hip, are most often involved, and up to half of patients ultimately require joint replacement.[649] Radiation-induced bone abnormalities, including osteochondromas and metaphyseal growth abnormalities, can occur after TBI-containing transplant regimens; younger patients appear to be at greater risk.[650] Childhood survivors of HSCT should be evaluated regularly to ensure that hormonal and nutritional status is optimized. The role of bisphosphonates in the treatment of these conditions is being investigated. Early data indicate that bisphosphonates can improve BMD, but long-term effects of this intervention in the pediatric population are unknown.[639]

CLINICAL APPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

Myelodysplasia/Juvenile Myelomonocytic Leukemia

The myelodysplastic syndromes (MDSs) are a heterogeneous group of clonal stem cell disorders that can progress to acute leukemia. These disorders are much more common in adults but also account for approximately 3% of childhood hematologic malignancies. This figure may be an underestimate because a subset of children presenting with de novo AML presumably had an antecedent MDS.[55] The FAB classification system is based on the proportion of leukemic blasts in the marrow; most pediatric patients have either refractory anemia (RA), refractory anemia with excess blasts (RAEB), or RAEB in transformation (RAEB-T). Juvenile myelomonocytic leukemia (JMML), a rare disorder of infants and young children, shares similarities with MDS, and a new classification system has been proposed that allocates pediatric patients with clonal myeloproliferative diseases into three groups: MDS, JMML, and myeloid leukemia of Down syndrome.[651] MDS and JMML are disorders arising from pluripotent stem cells, and thus allogeneic HSCT remains the only curative approach.

Even though patients with JMML are generally very young and should tolerate therapy, induction chemotherapy prior to HSCT is generally not recommended because remission is unlikely to be attained and toxicity is unexpectedly high.[652] Thus proceeding straight to HSCT is the recommended course. A BU- versus TBI-based conditioning regimen has been associated with a lower rate of relapse.[653,654] As transplant-related mortality has decreased, survival has improved, with recent consortium data reporting an approximately 50% 5-year DFS; relapse remains the greatest obstacle to cure.[654] *Cis*-retinoic acid appears to decrease the spontaneous proliferation of leukemic progenitor cells in JMML as well as abrogate their selective hypersensitivity to GM-CSF.[655] It is often given after HSCT as therapy for MRD, although efficacy has not been firmly established.[656] A small subset of patients may exhibit a milder phenotype of the disease, and rare reports exist of improvement without specific intervention. *RAS* mutations may be more common in this group,[657,658] or children may have had a viral illness mimicking JMML. The vast majority of children, however, exhibit persistent or progressive disease and should move expeditiously to HSCT once other diseases in the differential diagnosis have been excluded.

The role of induction therapy before HSCT for MDS is unclear and has never shown a convincing impact on outcome. Up to one half of patients can achieve remission after AML-directed therapy[659]; however, and this approach may decrease relapse in patients with increased blasts at presentation.[652] Conditioning with both TBI- and BU-based regimens has been used, with most studies showing no difference in outcome,[660] although some favor BU.[661] Overall, the strongest predictor of survival is stage of disease.[662,663] A child undergoing transplantation for RA/RAEB has an event-free survival (EFS) of around 70%; a patient with RAEB-T was five times more likely to experience relapse.[664] Currently, approximately half of pediatric patients with MDSs can be cured, and thus allogeneic HSCT should be considered early in the disease course.[665] A retrospective review of pediatric patients from a single institution demonstrated a 80% DFS for those receiving no induction therapy and going to HSCT within 140 days of diagnosis.[666]

Acute Lymphoblastic Leukemia

Improvements in chemotherapy regimens and supportive care have resulted in a steady increase in the cure rate for ALL, and approximately 85% of children are now cured by current risk-adapted chemotherapy regimens.[667,668] However, for patients with ALL who cannot be cured by standard-dose chemotherapy, HSCT remains the mainstay of treatment. Because HSCT can be very effective for patients with relapsed disease, there has been an increasing focus on identifying the clinical and biologic characteristics of patients who are at highest risk for relapse after standard-dose chemotherapy so that they can be referred for HSCT at the earliest possible point in their course before relapse occurs.

In newly diagnosed children with ALL, there are many clinical and biologic characteristics, referred to as "risk features," that are used to adapt the duration and intensity of chemotherapeutic regimens (Fig. 8-2).[669] However, a smaller number of features are used to identify newly diagnosed patients for whom allogeneic SCT should be the standard approach once remission first remission has been achieved. Patients with leukemia marked by a cytogenetic abnormality resulting from a reciprocal translocation of chromosome 9 and 22 (i.e., t[9;22]) known as Philadelphia chromosome–positive ALL (Ph+) have historically had a dismal prognosis when treated with standard-dose chemotherapy.[670,671] For these patients, matched-sibling HSCT in first remission significantly improved survival. A large European cohort found a relative risk of 0.3 for relapse or any adverse event with

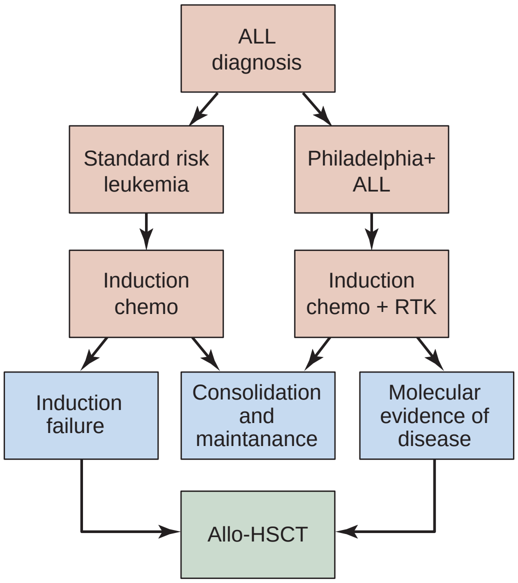

Figure 8-2 The role of hematopoietic stem cell transplantation *(HSCT)* in newly diagnosed acute lymphoblastic leukemia.

transplantation versus conventional chemotherapy[672] and a DFS of more than 60%.[673] Currently, most patients with Ph+ ALL undergo transplant in first remission using the best available donor, with 5-year EFS of 50% after mismatched family or UD transplant.[674] However, the treatment approach to Ph+ ALL has been evolving since the advent of tyrosine kinase inhibitor (TKI) therapy (see Chapter 51),[675,676] and the current recommendations for pediatric Ph+ ALL in first remission now suggest treatment with a combination of intensive CT plus TKI.[677] An emerging consensus is that HSCT should be reserved for newly diagnosed patients with Ph+ ALL who do not show molecular evidence of response.[678]

The role of transplant in first remission is less clear for other adverse cytogenetic abnormalities, including patients with t(4;11) translocation or hypodiploid ALL. Extreme hypodiploidy of less than 44 chromosomes is uncommon but results in an EFS of only 30% with standard chemotherapy.[679] This has led to the inclusion of patients with hypodiploidy in trials of HSCT in first complete remission,[673,680] although the numbers of hypodiploid cases are too small to make definitive statements about the impact of HSCT on outcome.

Historically, the outcome of patients with the T-cell phenotype of ALL has been worse than patients with precursor-B cell ALL, but those differences have largely been abrogated by the intensive chemotherapy used in modern protocols.[681] However, an attempt is ongoing to define high-risk patients within this group, usually in those with a very high white blood cell count at diagnosis. Some reports suggest that the outcome for this subgroup may be improved by transplant in first remission,[682,683] but this has not become standard of care in pediatric patients. It is not certain that the presence of a t(4;11) translocation is an adverse risk factor for children older than 1 year of age,[684] but infants who harbor this translocation have an almost fivefold increase in the risk for an adverse event compared with infants without an MLL rearrangement.[685] Even within this group further distinctions can be made: very young infants with MLL + ALL and a high white blood cell count at diagnosis have an EFS of less than 5%.[686] An international study of infant leukemia found that a poor prednisone response in addition to the previously mentioned factors identified those at the highest risk.[687] It is not definitively known if HSCT in first complete remission can improve the outcome of this group; however, single-center studies have reported an EFS of more than 60%[688,689] and the current version of the international consortium trial recommends HSCT in first remission for the highest-risk group of infants.[690,691]

Many studies have demonstrated the prognostic importance of the rapid clearance of leukemic cells in the peripheral blood or bone marrow during induction chemotherapy, and patients who have induction failure have a poor outcome. Historically, the presence of blasts was assessed histologically; however, more sensitive methods of flow-cytometric detection of leukemic blasts[692] or polymerase chain reaction amplification of transcripts for clonal immunoglobulin, T-cell receptor, or oncogenic fusion genes[693] has become standard. In a large European study, induction failure, defined as the persistence of leukemic blasts 4 to 6 weeks after induction chemotherapy, occurred in only 2.3% of newly diagnosed patients, but the overall prognosis for this group was poor, with a 10-year overall survival of 32%.[694] In this study, patients with induction failure and either T-cell ALL, MLL rearrangement, or age greater than 10 years had a particularly poor outcome and a clear benefit of HSCT over chemotherapy was demonstrated. However, for younger patients (age <6 years) with B-cell phenotype ALL and no high-risk genetic features, no benefit of HSCT was shown.

In summary, it appears that ALL patients with some high-risk features at diagnosis have a decreased incidence of relapse and improved survival when taken to HSCT from a matched RD in first complete remission and that HSCT confers the greatest advantage in the patients at highest risk.[682] However, it is likely that increasing numbers of targeted therapies for specific molecular subtypes of ALL will enter the early stages of therapy in the coming years, making the indications for HSCT in newly diagnosed ALL an evolving field.

Once ALL has recurred, the chance of cure drops dramatically.[695] A landmark study in the late 1980s concluded that HSCT from a matched RD cured approximately 40% of children with relapsed ALL. In contrast, conventional chemotherapy resulted in subsequent relapse over 90% of the time, establishing HSCT as the mainstay of therapy for relapsed ALL.[696] However, just as for newly diagnosed patients, clinical and biologic features strongly affect the likelihood of cure with HSCT versus further chemotherapy. The strongest predictors of outcome in patients with recurrent ALL are the duration of the first remission, T-cell phenotype, and the site(s) of relapse.[695] These features are most commonly used to identify the patients with relapsed disease most likely to benefit from HSCT.

Patients who experience an early relapse (defined variably as relapse occurring on therapy or within 18 to 36 months from diagnosis) present one of the most difficult challenges in ALL therapy. It is clear that chemotherapy alone cannot cure these patients, and most studies show a survival advantage for sibling HSCT.[697] However, the results for HSCT in patients with early relapse ALL are also poor: a report of children with a bone marrow relapse within 12 months of completing therapy found a 3-year EFS of approximately 25% regardless of treatment modality.[698] Most of the earlier discussed studies have been with matched sibling donors; as outcomes with alternative donors have improved, equivalent results with UDs are now being reported.[699,700] In summary, it has not been determined which patients with ALL in the second complete remission conclusively benefit from allogeneic HSCT. Patients with late isolated extramedullary relapses should not undergo transplantation in most circumstances. For the remaining groups there are no prospective randomized trials to guide therapy.

Some children are unable to tolerate the months of intensive therapy given in relapse protocols and then should be considered for HSCT,[700] because most studies reveal a lower incidence of relapse with transplant that often but not always translates into an improved DFS.[680,701] The risks and benefits of transplant must therefore be carefully considered in each situation, balancing type and match of available donor, medical condition of the patient, and patient and family preference.

Patients experiencing an isolated bone marrow relapse fare more poorly than those with either an isolated extramedullary relapse (usually involving the CNS or testes) or those with a combined extramedullary and bone marrow relapse. As a result, most children with an isolated extramedullary relapse occurring after chemotherapy has been completed are treated with intensive chemotherapy and irradiation to the site of relapse rather than allogeneic SCT. This strategy results in very good outcomes, with a recent consortium trial showing that approximately 75% of children in this situation can be cured using systemic and intrathecal chemotherapy and cranial irradiation.[702]

Acute Myeloblastic Leukemia

Successive clinical trials over the past 30 years have firmly established the role of intensive postremission therapy in the treatment of AML. However, there remains debate as to whether allogeneic HSCT or intensive chemotherapy without stem cell support is the optimum postremission therapy. Allogeneic HSCT offers dose-intensity and the possibility of graft-versus-leukemia effect but is not an option for all patients and comes with heightened risks for acute and long-term toxicities. Intensive chemotherapy without stem cell support is feasible for most patients and may have less toxicity. A recent retrospective assessment of 233 children with cytogenetically defined high-risk AML did not demonstrate a survival difference between those who received chemotherapy alone and those who received allogeneic HSCT.[703] In this study the risk for relapse was lower in the transplanted population and the transplant-related mortality rate was higher. The study included patients who underwent transplants between 1989 and 2006. It is likely that the transplant-related mortality is lower in the modern era owing to improvements in supportive care. It is possible that the reduced risk for relapse after transplant may outweigh the risk for transplant-related mortality in the modern era.

Allogeneic HSCT in first complete remission was first addressed in a series of prospective trials in the mid-1980s. In 111 consecutive patients, the Seattle group undertook matched sibling allogeneic HSCT for patients who had a donor whereas the remaining patients received conventional intensification. The probability of 5-year DFS was 49% for HSCT compared with 20% for chemotherapy alone.[704] However, since that time, more intensive postremission chemotherapeutic regimens have been associated with improved disease control in children and adults with AML.[705,706] This has again raised the question of whether allogeneic HSCT is more effective than intensive chemotherapy in the postremission setting. To address this issue the Children's Cancer Study Group conducted a large, randomized trial of allogeneic HSCT versus chemotherapy or autologous HSCT in 652 children and adolescents with AML who achieved remission. At the end of induction, patients with five or six HLA-antigen matched relatives were allocated to allogeneic HSCT. All others were randomized between autologous HSCT with 4-hydroperoxycyclophosphamide (4-HC) purging or four courses of chemotherapy. The results of this trial showed that the outcome with allogeneic HSCT was superior to that of either chemotherapy or autologous HSCT.[705] For patients treated with an intensive induction regimen, the DFS with allogeneic HSCT was 66%, compared with 53% with chemotherapy 48% with autologous HSCT.[705] These data underscore the benefit both of intensive induction chemotherapy and of first-remission matched sibling donor HSCT in the management of newly diagnosed AML for many patients.

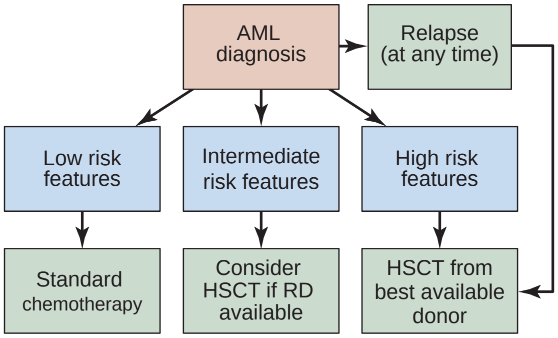

Figure 8-3 The role of hematopoietic stem cell transplantation *(HSCT)* in newly diagnosed acute myeloblastic leukemia.

Studies have attempted to identify groups of patients that are at increased risk for poor outcomes with chemotherapy alone in first complete remission for which HSCT would be beneficial. Investigators have shown that allogeneic transplant in first complete remission in patients can improve the outcome for children with high-risk prognostic features (Fig. 8-3).[707] In the pediatric population, consistent prognostic indicators are the response to initial induction therapy and cytogenetic markers.[708,709] Additionally, the presence of MRD before transplant has gained prognostic importance.[710-713] The Medical Research Council (MRC) AML-10 trial found 5-year survival rates of 67%, 65%, and 23% in patients who achieved complete remission, partial remission (5% to 15% blasts), and had residual disease, respectively.[708] The relapse rates in these groups were 34%, 38%, and 87%. This and other studies stratified patients based on favorable, intermediate, and adverse karyotypic abnormalities. Favorable karyotypic abnormalities include t(8;21), inv(16), t(15;17), and, in some studies, t(9;11) and t(16;16).[708,709,714,715] Adverse abnormalities include −5, −7, del(5q), abn(3q), and complex karyotypes.[715] Patients who have neither favorable nor high risk are considered of intermediate risk. In the MRC AML-10 trial, patients with favorable and intermediate karyotypic abnormalities had survival rates of 76% and 52% with relapse rates of 34% and 44%. This was compared with survival and relapse rates of 40% and 61% in patients with adverse karyotypes.[708] The MRC further designated risk groups of good, standard, and poor risk in the MRC AML-10 trial. The good-risk group included patients with favorable karyotypes or FAB type M3, irrespective of response status after one course of chemotherapy or the presence of other karyotypic abnormalities. The standard-risk group included patients in neither the good- nor poor-risk groups. The poor-risk group included patients with adverse karyotypic abnormalities or with resistant disease in the absence of favorable karyotypic abnormalities and not FAB type M3.[708] There was no significant difference in the percentage of deaths during first complete remission between any of the groups.[706] There were significant differences between the good, standard, and poor groups in regard to relapse-free survival (65%, 62%, and 36%), DFS (59%, 54%, and 32%), survival from relapse (61%, 17%, and 0%), and 7-year survival from complete remission (78%, 60%, and 33%). The 61% salvage rate after relapse in the good prognosis group suggested that HSCT in the first complete remission may be inappropriate for this group. Although not assessed in the MRC trial, patients with an activating *FLT3* mutation have been shown to have a poor prognosis and benefit from HSCT in the first complete remission.[373,716]

Several studies have suggested that the presence of high MRD at any point before HSCT leads to increased relapse rate.[710,711,713,717,718] Researchers at the Fred Hutchinson Cancer Research Center studied 253 patients and found that patients with even small levels of MRD before allogeneic myeloablative HSCT has a negative impact on overall survival in patients transplanted in both first and second complete remissions.[710] Rosenberg and associates investigated the impact of MRD on survival in 89 pediatric patients after myeloablative allogeneic transplant. The 3-year overall survival for patients with MRD positivity before transplant was 15%, compared with 67% in children without MRD. A prospective multicenter study is currently investigating the impact of MRD assessed before and at two time points after transplantation.

Autologous HSCT has been studied for patients who have no allogeneic donor. In many trials, autologous marrow was purged of residual leukemic cells with 4-HC, although no direct benefit of this technique has been proven. Multiple trials in adults and adolescents with AML suggest that autologous HSCT might offer additional therapeutic efficacy over chemotherapy.[659,719] Pediatric trials and a recent meta-analysis have not demonstrated any advantage to this modality in patients in first complete remission, and there are insufficient data to assess the influence of AML subclass on outcome.[720-724]

In most studies of patients with relapsed AML, the duration of first remission is strongly predictive of outcome, with the DFS of patients experiencing relapse less than 1 year after diagnosis 10% to 20% regardless of treatment modality used.[725,726] Early studies reported DFS of patients transplanted in untreated first ("early") relapse to be as high as 25% to 30%.[727,728] In contrast, a more recent report of 379 adults with relapsed or refractory AML found the DFS of patients transplanted in untreated first relapse to be no better than 13%.[729] Patients with treatment-refractory disease had an equivalently poor prognosis. However, the DFS for patients who were are able to go into a second remission was significantly better at 32%. The outcome of children with relapsed AML was studied by the MRC Childhood Leukemia Working Party.[725] Of the 81 patients in whom curative therapy was attempted, 69% went into a second remission. Approximately two thirds of these patients were consolidated with allogeneic HSCT, and the overall survival of the group was 44% at 3 years. Although this was not a randomized study, patients treated with HSCT had a longer duration of second remission than those treated with chemotherapy alone.[725] These data support the use of allogeneic HSCT in the treatment of relapsed AML, especially for those patients who can achieve a second remission.

Chronic Myelogenous Leukemia

CML is a proliferative stem cell disorder arising from a translocation between chromosomes 9 and 22 (t(9;22)) known as the Philadelphia chromosome. The only curative therapy for this condition is allogeneic HSCT. However, with the advent of targeted molecular therapies such as imatinib, a TKI, daily administration of an oral agent can control the disease for years, if not longer, with minimal side effects. As a result, the role of HSCT with the attendant short- and long-term toxicities is being redefined. The majority of the literature on both HSCT and TKI therapy reflects studies in adults in which current practice is to use TKI as initial therapy in virtually all patients presenting with chronic-phase CML.[730] A French prospective trial has shown that imatinib has similar efficacy in the pediatric population.[731] However, the risk-benefit profile remains different in the pediatric versus adult population; the results of transplant are better than in adults owing to both decreased transplant-related mortality and GVHD and the implications for both compliance and toxicity of decades of daily therapy are not yet well understood. In the largest pediatric transplant series to date patients receiving either matched sibling donor (n = 182) or UD (n = 132), HSCT had a 63% and 56% DFS, respectively. The best outcome was observed in those going to transplant in the first chronic phase and within 6 months of diagnosis; DFS with a sibling donor for that cohort was 73%.[732] Given these data and newer studies showing outcomes to be virtually identical with sibling donors or UDs for pediatric leukemia patients, it still may be reasonable to offer HSCT as the first therapeutic intervention for select pediatric patients with either a sibling donor or fully matched UD. However, the most common approach is to begin TKI therapy at the time of diagnosis with careful monitoring of disease response. Robust data now allow response to imatinib at specific time points to be categorized as "failures," thus identifying patients who need alternative therapies.[730,733] In young patients, whether the next intervention should be allogeneic HSCT or a trial of second-generation TKIs depends on donor availability and physician and family and patient assessment of the risks and benefits attendant on both strategies. However, given the paucity of efficacy and safety data on second-generation TKIs in the pediatric population, proceeding to allogeneic HSCT is currently the most conservative approach.[734] The rare patients who present in accelerated phase or myeloid or lymphoid blast crisis of CML have a much worse prognosis and require lymphoid- or myeloid-directed chemotherapy to try to attain a chronic phase followed by HSCT. Allogeneic HSCT historically offered curative therapy for approximately 40% of such patients.[63,735] The addition of TKI therapy both before and after HSCT has favorably impacted relapse in early studies.[736]

For those patients undergoing HSCT, careful monitoring of disease status remains an essential component of posttransplant care.[737] Relapse detected when disease is confined to cytogenetic or molecular positivity responds extraordinarily well to infusions of donor lymphocytes (DLI). Currently, most patients receive escalating doses of CD3+ T cells in an attempt to achieve disease control without inducing GVHD.[738] TKI administration for post-HSCT recurrences—either alone or in combination with infusions of donor lymphocytes—is still being evaluated but seems to be generally well tolerated and may favorably impact outcome.[739-741]

Hodgkin and Non-Hodgkin Lymphoma

Autologous HSCT has been utilized in children with Hodgkin disease (HD) or aggressive non-Hodgkin lymphoma (NHL) in the setting of refractory or recurrent disease after conventional therapy. Both TBI-based and chemotherapy-only approaches have been used with equal success. Autologous PBSCs as compared with bone marrow are the preferred stem cell source based on earlier engraftment for both neutrophils and platelets.[742] The ability of high-dose therapy with autologous rescue to salvage pediatric patients with Burkitt lymphoma was established in 1986, when a 5-year French experience demonstrated approximately 50% DFS.[743] Similar results in children with Burkitt and large cell lymphoma as well as HD have been reported more recently from other European centers and in larger combined pediatric and adult series.[744-748] Paralleling the findings in adult patients with lymphoma, the DFS is most consistently affected by the presence of chemotherapy-sensitive disease before HSCT; long-term survival is unlikely in those with resistant bulky disease at the time of HSCT.[749] Length of first remission (< or >12 months) also appears to impact survival.[750] The addition of rituximab before and/or after HSCT for B-cell lymphomas may further improve outcome in this group of patients,[751,752] although a more recent study of almost 500 adult patients failed to show a decrease in relapse with the addition of rituximab maintenance therapy after autologous HSCT.[753] Refractory or relapsed T-cell lymphoblastic lymphoma is treated identically to T-cell ALL, and allogeneic HSCT from the best available donor is the standard approach; achieving remission with salvage therapy is essential to have the potential for cure.[111]

There has been long-standing interest in the role of allogeneic BMT in the treatment of relapsed/refractory NHL and HD, although the balance of risk and benefit is still frustratingly unclear because most series show a decreased rate of relapse but increased transplant-related mortality.[754] Retrospective studies in adult/pediatric series suggest that ultimately the results are comparable.[755] A prospective trial confirmed lower relapse rates in allogeneic BMT but no overall survival advantage, owing to significant transplant-related mortality. As seen in patients undergoing autologous HSCT, chemosensitivity before the transplant procedure was the major prognostic factor affecting outcome.[756] The advantage conferred by an allogeneic stem cell source may be dependent on the type of lymphoma; a recent study of pediatric patients with anaplastic large cell lymphoma reported a remarkable 75% DFS, with successes even in patients experiencing relapse after autologous HSCT.[757] Whether the decrease in relapse rate reported in these studies reflects a graft-versus-lymphoma effect or merely the infusion of uncontaminated HSCs is not clear.[758] The introduction of reduced-intensity approaches can decrease transplant-related mortality, but this is often at the expense of an increased incidence of relapse.[759] Characterization of patients at particularly high risk for failure should allow better delineation of which patients could benefit from an allogeneic transplant—either alone or as a tandem approach after autologous transplant[760]—despite the increase in transplant-related mortality and the risk for cGVHD.

Neuroblastoma and Other Solid Tumors

The biology and treatment of pediatric solid tumors are discussed elsewhere in this text (see Section XV). The most extensive HSCT experience in pediatric solid tumors is in patients with advanced-stage neuroblastoma. Historically, patients receiving conventional doses of chemotherapy almost always succumbed to disease. In 1999, a landmark trial showed a significant improvement in DFS (34% vs. 22%) for patients randomized to consolidation with autologous BMT compared with continued intensive nonmyeloablative chemotherapy.[761] Regimen-related toxicity was acceptable, and dose intensification appeared to impact DFS; thus sequential or “tandem” transplants were investigated utilizing two[762] or three[763] cycles of non–cross-resistant agents over a short period of time with autologous PBSC support after each cycle. It appears that such approaches can further improve outcome, with reported 3-year DFS of 58%[762] and an estimated DFS of 45% at 7 years from diagnosis.[764] Relapse remains a significant problem primarily at diffuse osseous sites. Neuroblastoma cells marked in the stem cell product have been identified at sites of relapse,[167] and a variety of positive and negative selection techniques have been employed to purge the stem cells before reinfusion, although no technique has been definitively shown to impact outcome; profound depletion of T cells from the graft has, however, resulted in an increase in life-threatening viral infections.[765] Current efforts have focused on selecting a conditioning regimen that provides the greatest additive effect for disease control. Early results from a European randomized trial suggested that the incidence of relapse was lower in children receiving a BU/melphalan approach as compared with the carboplatin-based approach used in the United States. The ongoing national Children’s Oncology Group trial is evaluating this regimen. There are insufficient data to address efficacy; toxicity has been acceptable, although the incidence of severe VOD appears to be increased.[766] There has been long-standing interest in the role of allogeneic transplant for high-risk neuroblastoma. A retrospective study from the international registry did not demonstrate any impact on relapse rate or survival.[767]

Therapy for MRD after HSCT is essential. The use of *cis*-retinoic acid as a differentiating agent adds minimal toxicity and favorably impacts relapse.[761] A recent randomized trial unequivocally demonstrated the role of anti-GD2 antibody therapy after HSCT with significant improvement in both overall survival and DFS.[768] The trial met criteria for early stopping owing to demonstrated efficacy, and the ethical issues surrounding this relatively rare event are nicely reviewed by Unguru and colleagues.[769]

Most children undergoing autologous HSCT for neuroblastoma are very young, and there have been concerns about their quality of life after this intensive therapy. However, it appears that most survivors of this previously almost uniformly fatal disease are neuropsychologically intact. Survivors are at risk for a variety of medical complications, the most common being short stature, gonadal failure, and hearing loss (seen in three fourths of patients)[770,771] and must be closely followed by appropriate specialists to optimize outcome.

The role of high-dose therapy with autologous PBSC rescue for brain tumors is still being evaluated. The literature is most extensive for those tumors with a clear chemotherapy dose-response curve such as medulloblastoma/primitive neuroectodermal tumor and germ cell tumors.[772-775] HSCT is most often employed in the setting of recurrent disease but is occasionally used at the time of first remission in patients with adverse prognostic features or in very young children in an attempt to avoid radiation therapy.[776,777] The EFS ranges from 25% to 60%; and, as is the case for most conditions treated with autologous HSCT, those with no detectable disease at the time of transplant fare best. Ongoing consortium trials hope to standardize therapy and better delineate which patients can benefit most from this therapeutic approach.

Small single-institutional series have been published on the use of either allogeneic or autologous HSCT for other nonhematologic malignancies. Some promise in terms of response rate has been observed for patients with sarcomas who have both MRD and chemosensitive disease,[778,779] but the generalizability and durability of these responses will need to be established before widespread application can be supported.

Immunodeficiency Disorders

Since the late 1960s, allogeneic BMT has been successfully employed to cure children with a number of lethal immunodeficiency diseases, including severe combined immunodeficiency disease (SCID) and Wiskott-Aldrich syndrome.

Severe Combined Immunodeficiency Syndromes. SCID is a clinical syndrome arising from a variety of genetic abnormalities that all result in profound deficiencies in T-cell function.[780] At least 18 types of SCID have been identified that vary in the affected gene but share as a common feature a profound effect in T-cell development or function. Differences in the genetic basis of SCID results in a spectrum of abnormalities that may also affect B cell[781] and NK cell number and function.[782] In classic X-linked SCID there is profound T-cell lymphopenia and a variable number of nonfunctioning B cells whereas patients with adenosine deaminase deficiency lack B cells, T cells, and NK cells. Autosomal recessive SCID phenotypes have different combinations of B-cell and NK-cell presence.

Without effective therapy, the outcome of SCID is invariably fatal[782] and HSCT has become the mainstay of therapy for most types of SCID, with long-term survival as high as 90% of patients.[783-786] Unlike most transplant settings, owing to the underlying immunologic defect, SCID patients with a matched RD do not necessarily require conditioning.[787] After infusion of genotypically matched donor HSCs without cytoreduction, immune reconstitution will take place within several weeks and evidence of good lymphocyte function will be evident by 2 to 3 months.[788] Significant aGVHD or cGVHD is uncommon. Dramatically improved long-term survivorship from the range of approximately 50% in the 1970s to over 90% currently appears attributable to more rapid and precise diagnosis, followed by transplant of patients at a younger age and in better condition, and to improved supportive care for the associated infectious complications.[784,787]

The optimal approach for children lacking a matched sibling donor is less clear, and two different strategies have been employed: T-cell–depleted haploidentical transplant usually using a parent as the donor or transplant from a matched UD or UCB unit. Early experience with haploidentical HSCT was hampered by graft rejection, frequent severe GVHD, and opportunistic infection, resulting in poor long-term survival.[784,789] The advantage of this approach is that neither cytoreductive therapy nor GVHD prophylaxis is needed and thus peritransplant mortality is low. However T-cell function usually takes several months to appear, patients generally do not have B-cell function mandating lifelong intravenous immune globulin replacement, and graft rejection necessitating a second or even third transplant occurs in approximately 20% of patients.[790] T-cell function normalized and was most robust in children diagnosed early and undergoing transplant within the first 28 days of life,[791] thus increasing the importance of screening initiatives to diagnose SCID in the neonatal period.[792,793]

Given the concerns about haploidentical transplantation, there is increasing interest in using of matched UDs as a stem cell source for those patients lacking a matched sibling donor. Although cytoreductive conditioning is required with this approach, it may allow the more rapid reconstitution of a fully-functional donor immune and hematopoietic system.[789] These advantages must be weighed against the time taken to identify a UD and the risk for GVHD, the increased risk for acute infectious morbidity and mortality associated with myeloablative therapy, and the long-term sequelae, including the likelihood of infertility. Recent reports indicate that use of a UD confers a survival advantage compared with mismatched RDs (80% vs. 52%) as well as improved reconstitution of a full T-cell repertoire.[784] The role of nonmyeloablative HSCT and the ability of this approach to decrease acute toxicity and mitigate long-term sequelae is being investigated but may be a particularly attractive option in children with severe organ dysfunction at the time of HSCT.[794]

Wiskott-Aldrich Syndrome. Wiskott-Aldrich syndrome is an X-linked disorder in which progressive T-cell immunodeficiency is associated with eczema, small platelets, and absolute thrombocytopenia. The pathogenesis of this disorder is associated with aberrant expression of the WAS protein, which is involved in cytoskeletal organization as well as T- and NK-cell activation.[795] (See Chapter 24.) Both TBI-containing and BU-based regimens have successfully been used in conditioning patients with Wiskott-Aldrich syndrome, and the reported survival rates of almost 80% to 90% in patients are among the best of any patient cohort undergoing allogeneic SCT.[786,796] A recent collaborative study demonstrated 84% survival in 194 patients with Wiskott-Aldrich syndrome treated with HSCT,[796] although almost a fourth of patients did not have full donor chimerism at a year, suggesting that additional improvements in outcome may accrue from optimized conditioning regimens. Thus most children afflicted with Wiskott-Aldrich syndrome are now expeditiously referred for transplantation using the best available donor, with a palliative approach including splenectomy and chronic intravenous administration of immune globulin being utilized only in rare cases.

In summary, outcomes for patients with primary immunodeficiencies treated with HSCT are improving, as a result of better donor selection, optimal supportive care, and early diagnosis, but the field is still an evolving one, and the relative roles for HSCT from different donor sources—and the use of gene therapy for some diseases—are likely to change with time.

Hemoglobinopathies

Sickle Cell Disease. Allogeneic HSCT offers a curative approach for patients with sickle cell disease (SCD). Because the clinical course of SCD is highly variable and, particularly with the advent of pneumococcal prophylaxis, childhood morbidity and mortality is low, HSCT as a treatment modality has been relatively slow to gain widespread acceptance. Initial studies offered HSCT to the subgroup of patients with the most significant symptoms: stroke, recurrent acute chest syndrome, or frequent painful crises. In the seminal report by Walters, DFS after BU-based myeloablative conditioning was 73% and overall survival was 91% at 4 years; end organ damage was stabilized in patients with sustained donor engraftment.[797] Improved management of transplant complications in general and increased attention to SCD specific toxicities (e.g., additional immunosuppression to decrease graft rejection, antiseizure prophylaxis, strict management of hypertension) have resulted in consistent gains in cure rates,[798] with EFS of more than 95% in patients undergoing a transplant after January 2000.[799,800] Meticulous long-term assessment of these patients has demonstrated that successful engraftment will protect against progressive pulmonary and CNS disease but significant gonadal toxicity is sustained.[801] Newer approaches such as the use of hydroxyurea to decrease the risk for graft rejection by impacting pretransplant bone marrow cellularity[802] or the use of a nonmyeloablative approach to decrease transplant-related morbidity and mortality[803] or even preserve fertility require both larger numbers of patients and longer follow-up before being considered as a standard approach. Early results suggest that reduced-intensity conditioning results in mixed chimerism for most patients but is associated with sufficient erythroid engraftment to reverse the sickle phenotype.[804,805] HSCT has historically been considered only for patients who have an available matched sibling donor. A multiinstitutional survey of factors impacting the use of HSCT in this population found that less than 15% of affected children had an acceptable sibling donor.[798,806] The role of UD HSCT in patients with the most severe manifestations of disease or in those unable to receive long-term transfusion therapy is unknown, but multiinstitutional trials are currently ongoing with a reduced-intensity conditioning platform.[800] The use of unrelated UCB is a theoretically attractive option given the decreased incidence of GVHD and the ability to identify acceptable donors for patients with less common HLA typing by tolerating greater HLA disparity. Small numbers of transplants have been reported with successful outcomes, but graft rejection remains an obstacle to widespread use and resulted in early closure of the UCB arm of the ongoing national trial.[807,808]

The choice to proceed to matched-sibling HSCT remains complicated, particularly if complications of the disease are moderate or intermittent. There are no prospective randomized trials to inform the decision and therapy with hydroxyurea, chronic transfusions and HSCT each have associated risks and benefits. HSCT clearly has the highest upfront risk but also offers the only curative modality. The Belgian experience illustrates that children undergoing transplants at a young age before significant complications occur do best, with a DFS of 93% and overall survival of 100%,[809] and serious manifestations of SCD impacting on long-term survival such as pulmonary hypertension continue to be identified. Unfortunately, patients undergoing HSCT and who are cured of SCD remain at risk for complications from the transplant process: infertility is likely,[810] and the development of extensive cGVHD is a rare but potentially devastating possibility.[799] Patients (when of an appropriate age) and parents must be aware of the possible therapeutic options, thus allowing them to be educated and active participants in the decision-making process.[811-813]

Thalassemia. Thalassemia major (or Cooley anemia) is the most common transfusion-dependent anemia in the world. Chronic transfusion therapy and chelation to prevent the associated iron overload have modified the natural history of thalassemia and transformed a diagnosis that was uniformly fatal in early childhood into a chronic disease that is usually manageable, although progressive end organ dysfunction still develops.[814,815] Over time, even medically compliant patients are at risk for complications, including endocrine dysfunction, hepatic cirrhosis, cardiac disease, and transfusion-associated viral infections. In the developed world with sophisticated medical management, life expectancy is 25 to 55 years; compliance with chelation therapy is the most important factor impacting survival. Although advances have been made in supportive care over the past decade with resulting increases in life expectancy, in the developing world the majority of patients still die before the third decade of life.[814,816]

The successful application of HSCT as a curative approach for thalassemia major was first reported in 1982.[817] Subsequently, a very large experience reported by Lucarelli and coworkers[51] unquestionably established the feasibility of HSCT for thalassemia, and more than 3000 patients worldwide have now received transplants,[818] with the overwhelming majority using a matched sibling donor and a BU-based conditioning regimen.[819] The Pesaro classification system, based on the presence of hepatic fibrosis as assessed by liver biopsy, degree of hepatomegaly, and a history of inadequate chelation, allows risk stratification of potential transplant patients younger than 17 years of age: class I patients have no risk factors, class 2 patients have one or two risk factors, and class 3 patients have all risk factors. The risk factors used by Lucarelli and coworkers may be difficult to reproduce. The probabilities of overall survival, thalassemia-free survival (TFS), and graft rejection for patients undergoing HSCT from a matched family donor were 94%, 94%, and 0%, respectively for class I patients and 80%, 77%, and 9% for class 2 patients. Class 3 patients had only a 53% TFS owing to both increased graft rejection and transplant-related mortality.[51,820] Newer approaches based on increased immunosuppression using hydroxyurea, azathioprine, and/or fludarabine have yielded improved results for class III patients, with a TFS of 80% in patients younger than age 17 years.[821] Post-HSCT management of preexisting hepatic and cardiac iron overload and viral infections is essential for optimal outcome. Positive effects on bone mineral density in children may be seen after successful engraftment,[822] and even reversal of cirrhosis has been reported.[823,824] Impressively, a large study reporting on the quality of life of patients older than age 20 years after HSCT demonstrated that overall quality of life was identical to that of the general population for the majority of patients. Older age at HSCT and the presence of GVHD predicted a poorer quality of life. Interestingly, a matched cohort of thalassemic patients treated with transfusion/chelation reported a significantly worse quality of life when compared with transplanted patients.[825]

Although matched sibling HSCT has been shown to provide curative therapy for more than 90% of patients, the decision to accept the short- and long-term risks associated with HSCT remains complex and should occur on an individual basis after consultation with both hematologists and transplant physicians. Historically, patients lacking a matched sibling donor were not offered the option of HSCT because transplants using alternative donors conferred a dismal prognosis in this disease.[826] However, improvements in HLA typing, approaches to pre-HSCT preparative regimens, and supportive care have globally impacted transplant outcomes; thus alternative donor transplantation is now a reasonable option for selected patients. After mirroring results using sibling donors, it was shown that the best results occur in those with less-advanced disease, and a TFS of 80% to 100% for class I or II patients has been reported in small series.[827,828] Progress has occurred in the use of alternative donors in patients with advanced-stage disease as well. A recent small study using mismatched RDs and a preparative regimen emphasizing immunosuppression achieved a TFS of 94%.[826] A larger Italian study of 60 patients, two thirds of whom received transplants from UDs, employed a treosulfan-based preparative regimen and had a 5-year TFS of 84%, likely owing at least in part to the decreased hepatotoxicity of treosulfan compared with BU. There was no effect of Pesaro class or donor type (sibling vs. unrelated) on outcome.[829]

Thalassemia is a major global health problem because it is now most prevalent in resource-poor countries, with more than 100,000 affected children born annually in the Middle East and Southeast Asia. These countries lack the infrastructure to provide safe transfusions and/or chelation therapy, and the majority of children die before reaching adulthood.[830] The development of safe and affordable transplant strategies that can provide a cure for these patients is one approach to this important problem.

Osteopetrosis

Infantile malignant osteopetrosis is a rare disorder of osteoclast function that affects 1:200,000 to 1:300,000 children.[831-834] Osteoblast function is preserved, and the osteoclast dysfunction leads to an inability to resorb and remodel bone. The resulting osteoblast-osteoclast imbalance results in the formation of excessive mineralized bone and cartilage. Infantile malignant osteopetrosis is inherited in an autosomal recessive or autosomal dominant manner and causes severe phenotypes.[831,834,835] There is significant phenotypic variability dependent on the patient's genetic mutation. Commonalities in all phenotypes are poor growth and bony encroachment on optic and other cranial nerve foramina causing vision and hearing impairment. Eradication of the marrow space ensues, with progressive pancytopenia, failure to thrive, and hepatosplenomegaly.[831] In addition, patients with *CLCN7* autosomal recessive mutations suffer from progressive neurodegeneration and do not benefit from HSCT.[831,835] Murine studies revealed that osteoclasts arise from hematopoietic precursors of the monocytic lineage, and disease reversal was accomplished by engraftment of bone marrow from unaffected animals.[836] Successful HSCT in humans was first reported in 1977, and its applicability has subsequently been shown in many reports mostly using myeloablative BU-based conditioning regimens.[831,834,837,838] The European Group for Blood and Marrow Transplantation (EBMT) reported the long-term outcome of 122 children undergoing allogeneic HSCT between 1980 and 2001.[839] The 5-year DFS rate was 73% in those receiving transplants from an HLA-identical sibling versus approximately 40% in those receiving transplants from mismatched family donors or matched UDs. The major causes of failure were lack of engraftment, attributed in part to disruption of the underlying marrow microenvironment, and pulmonary complications, particularly pulmonary hypertension. Conservation of vision was most likely in those who underwent transplantation before 3 months of age. Patients, especially those older than 2 years at transplantation, are at risk for hypercalcemia as engraftment occurs, and therefore meticulous monitoring of calcium levels is essential in the peritransplant period.[838,839] At present, HSCT is the only curative option, although calcitriol, interferon-γ, and prednisone have been used to slow progression, ameliorate symptoms, or both.[840-842] Donor identification and subsequent HSCT should occur expeditiously as soon as the diagnosis is confirmed. Unless an unaffected, matched sibling is readily available a UCB unit may be preferred because it can be obtained in a more expeditious manner compared with a UD search because neurologic impairment can occur rapidly and may be irreversible, even with successful hematopoietic engraftment.

Transplantation for Lysosomal and Perioxisomal Diseases

Allogeneic transplantation is a therapeutic option for children with select inherited lysosomal and perioxisomal disorders.[843] These are rare diseases, and there are fewer than 100 transplants performed for these disorders annually in the United States.[4] Two key principles for transplanting children with lysosomal and perioxisomal diseases are that in most cases neurologic function lost before HSCT cannot be restored and because of this children with advanced disease do not benefit from transplant.

The mucopolysaccharidoses (MPSs) are inherited diseases caused by gene defects that result in the deficiency of lysosomal enzymes needed to degrade glycosaminoglycans (GAGs).[844,845] This causes cellular accumulation of GAGs and end organ tissue damage.[844,845] Treatment of MPS can include therapy of organ-specific defects, enzyme replacement therapy when available, and HSCT. Enzyme replacement therapy is currently available for MPS types I, II, and VI, is typically given as monthly infusions, and can be complicated by infusional reactions.[846-848] Enzyme replacement can improve the nonneurologic performance status and organ function but does not cross the blood-brain barrier and is ineffective for CNS disease.

The success of transplantation for the MPSs is based on correction of the enzyme deficiency, enzyme cross-correction, and the ability of hematopoietic cells to engraft and distribute as macrophage-derived tissue cells (e.g., microglial cells in the brain and Kupffer cells in the liver).[845,849,850,851] The correction of enzyme deficiency is mediated by donor leukocytes that engraft in the host tissue and secrete the missing enzyme. The leukocytes may enter the tissue directly, or secreted enzyme may enter the circulation. CNS therapy relies on donor cells crossing the blood-brain barrier. Enzymatic cross-correction is based on the principle that healthy cells secrete enzyme and can correct the biochemical consequences of enzymatic deficiency in neighboring cells.[851]

Clinically, the MPSs are characterized by CNS compromise and potential involvement of the skeletal system, heart and heart valves, connective tissue, facial structure, cornea, retina, upper airway, and liver.[844] Adverse effects on growth and development are common.[851] The pattern of organ damage is specific to each disorder, as is the response to transplant; and transplant is not effective for all diseases in this class.[843,845,849,850]

Allogeneic transplantation is best established and most successful for MPS I (Hurler syndrome) and is considered investigational for the other diseases.[850] Transplantation does not correct all manifestations of MPS I. It can correct upper airway obstruction, hepatosplenomegaly, and corneal clouding and may improve hydrocephalus, hearing dysfunction, and abnormalities of growth and development.[852] It is least effective for skeletal disease. The majority of published reports of transplantation for MPS I use non–radiation-containing myeloablative regimens.[843,845,849-851,853] There is debate about the most appropriate stem cell source to use for transplants in children with MPS I. A recent investigation of the transplant outcomes of 258 children with MPS I found that chimerism and enzyme levels were superior when an HLA 6/6 UCB unit was used compared with all other donor sources combined, including matched sibling donors.[853] However, siblings who were disease carriers were included in the analysis and may contribute to lower enzyme levels in the matched sibling group.

Sphingolipidoses are a group of lipid storage disorders related to sphingolipid metabolism and include Tay-Sachs, Niemann-Pick, Fabry, Gaucher, and Krabbe diseases and metachromatic leukodystrophy (MLD).[849] Enzyme replacement therapy is available for Fabry and Gaucher diseases, and with this therapy patients with these diseases can live into adulthood.[848] Despite having similar pathophysiology to the other sphingolipidoses, enzyme replacement therapy is not available for Krabbe disease or MLD and HSCT is the only potentially curative option for these patients.[854-857] Both Krabbe disease and MLD have early onset/infantile forms that can be successfully treated if children undergo a transplant when asymptomatic or with few symptoms.[858-860] Late onset forms of the diseases can be stabilized if symptoms are present, but not in the setting of advanced disease.[859,860]

X-linked adrenoleukodystrophy (ALD) is a perioxisomal disorder characterized by adrenal gland dysfunction, progressive inflammatory demyelination of the brain, and chronic axonal degeneration of the spinal cord.[861,862] The gene responsible for the clinical manifestations of ALD is mapped to Xq28 and encodes for the perioxisomal half-transporter ABCD1. The transporter plays a key role in the metabolism of very long chain fatty acids (VLCFA). The dysfunction of ABCD1 prevents the degradation of VLCFA and results in their tissue accumulation.[862]

Cerebral ALD is the most severe phenotype of the disease. Boys with ALD have a 60% lifetime risk for developing the phenotype, which is asymptomatic in the early stages. Progression is characterized by MRI changes, emotional lability, impaired visuospatial function, cognitive deterioration, hemiplegia or quadriparesis, and a vegetative state followed by death within 2 to 5 years after the onset of symptoms.[861,863] MRI change is evaluated by the Loes severity system, with lower scores having less disease burden.[864]

Therapeutic strategies in cerebral ALD include metabolic correction of the VLCFA accumulation with non-VLCFA (e.g., Lorenzo's oil and walnut oil), adrenal replacement, antioxidant supplementation aimed at reducing CNS inflammation that accompanies the disease, and allogeneic HSCT.[863] Allogeneic HSCT is currently the only nonexperimental, potentially curative option for boys with progressive cerebral ALD.[865,866] The precise mechanism of effect is not clear. Proposed mechanisms include correction of the metabolic defect in the CNS, the presence of donor microglial cells in the brain, and decreased inflammatory and immunologic reactions that contribute to disease progression. Similar to MPS disorders, the neurologic deterioration present before transplant cannot be recovered and the disease can progress for months after successful HSCT. Overall survival is best when transplant is performed in boys with few or no neurologic deficits, low Loes score, and use of an RD.[843,865-867] Because of this it is essential that transplant occurs as soon as disease progression is detected by MRI screening or symptom development.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a potentially life-threatening condition of severe inflammation caused by uncontrolled proliferation of lymphocytes and macrophages. HLH can be classified as primary or secondary based on the presence of a genetic mutation in primary disease.[868] Secondary disease develops in response to an infectious, rheumatologic, malignant, or other stimulus.[869-872] HLH typically presents as fever, hepatosplenomegaly, and cytopenias.[873] Other features include hypofibrinogenemia, hypertriglyceridemia, hepatic dysfunction, hyperferritinemia, neurologic symptoms, low NK cell activity, and elevated soluble IL-2 receptor levels.[873-878] Allogeneic HSCT is the only curative option for children with primary HLH. The estimated overall 3-year probability of survival after HSCT for patients treated on protocol HLH-94 was 64%; 71% ± 18% with matched RDs, 70% ± 16% with matched UDs, 50% ± 24% with family haploidentical donors, and 54% ± 27% with mismatched UDs.[879] Transplant conditioning has historically been with BU-based myeloablative regimens.[880-884] Unfortunately, fully myeloablative regimens are associated with transplant-related mortality rates of approximately 25%.[880,881,883,884] Reduced-intensity regimens are being used by some centers in an attempt to decrease acute toxicity and currently are being investigated in the multiinstitutional setting.[885-887] Reduced-intensity regimens are associated with an increased risk for mixed chimerism and frank graft failure and thus may not be appropriate when UCB is the only potential stem cell source.[885-887]

Treatment of Bone Marrow Failure—HSCT in Congenital and Acquired Bone Marrow Failure Syndromes

Acquired Aplastic Anemia. Severe aplastic anemia (SAA) is a syndrome characterized by peripheral pancytopenia and marrow hypoplasia (see Chapter 6). Mortality associated with this disorder in children was historically as high as 50% in the first 6 months.[888] Although a number of immunosuppressive and marrow stimulatory therapies have shown reasonable activity, the only curative treatment remains SCT. The potential efficacy of allogeneic SCT for patients with SAA was established with the initial publication in 1972 of results achieved in four patients (Fig. 8-4).[889] Randomized studies have since established the superiority of matched allogeneic SCT over supportive care (androgens in the 1970s, immunosuppressive therapy with antithymocyte globulin in the 1980s and 1990s) in both children and, more recently, adults.[890-893] In the setting of a matched sibling donor, the role of pre-HSCT conditioning is mainly to provide immunosuppression. CY in combination with antithymocyte globulin is the standard regimen, with cyclosporine and short-course methotrexate for GVHD prophylaxis. This approach cures almost 90% of patients with none of the sequelae associated with radiation-containing regimens.[894,895] Stem cell source has traditionally been bone marrow, but many centers have switched to peripheral blood progenitor cell grafts for ease of collection and faster engraftment kinetics. In a retrospective study of European and American registries, patients younger than 20 years of age had increased risk for cGVHD and higher overall mortality with peripheral blood cell versus bone marrow grafts.[896] Immunosuppressive therapy before matched sibling HSCT leads to an inferior outcome, mostly owing to increased rates of graft rejection.[897]

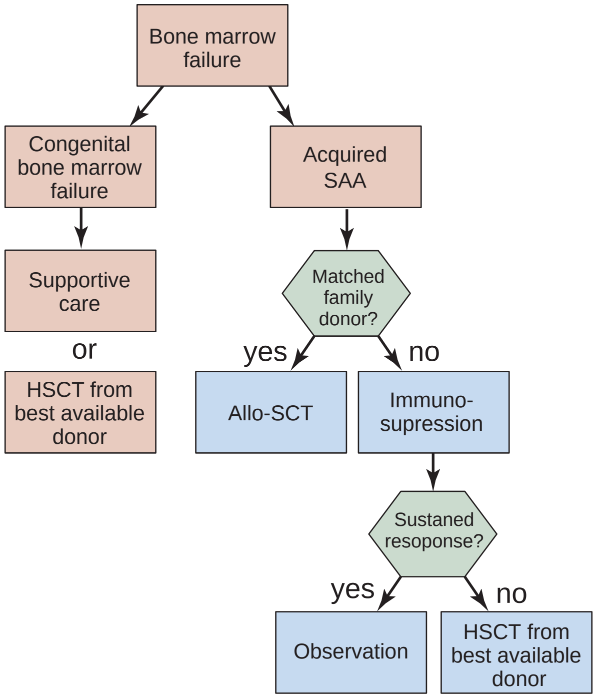

Figure 8-4 The role of hematopoietic stem cell transplantation *(HSCT)* in bone marrow failure syndromes.

Young patients with SAA receiving a non–radiation-containing regimen should have preserved fertility after HSCT.[898] In addition, long-term survivors exhibited few late effects[899] and were indistinguishable from healthy controls in terms of reported health, educational achievement, and psychosexual functioning.[900] Given these data and the expected excellent outcomes, patients with SAA and a matched sibling donor should be referred expeditiously for BMT, thus minimizing the number of pre-HSCT transfusions and the risk for acquiring serious infections.

Children who lack a matched sibling donor receive immunosuppressive therapy usually consisting of antithymocyte globulin, cyclosporine, and corticosteroids in an attempt to restore normal hematopoiesis. Up to 70% of patients will respond at 6 months, but only approximately 30% will have durable responses and remain transfusion independent. Additionally, a proportion of patients do not respond and responders remain at risk for both relapse of SAA and for evolution to MDS/AML.[901,902] The first reports of UD transplants for SAA used preparative regimens similar to those used with sibling donors. Results were very discouraging with graft rejection, transplant-related toxicity, and GVHD all being significant problems and survival rates less than 40%.[903] The incorporation of TBI into the conditioning regimen decreased the incidence of graft rejection and led to better results in some reports at least in part related to differences in patient condition, number of transfusions, and time from diagnosis to transplant.[904] In the era of improved HLA typing and better transfusion strategies, attempts have been focused on decreasing the intensity of the conditioning regimen and encouraging results have been reported with CY, antithymocyte globulin, and TBI doses as low as 200 cGY.[905] The addition of fludarabine or alemtuzumab with potent immunosuppressive properties and minimal organ toxicities may allow a radiation-free approach that could decrease both short- and long-term toxicities.[906,907] However, the experience with these approaches is still limited and long-term results, including durability of donor engraftment, remain to be evaluated. As conditioning regimens become less intense and outcomes using alternative donors approach those seen with sibling donors,[908] the optimal time to refer SAA patients for alternative donor transplant requires ongoing evaluation. As suggested by the results of a Japanese prospective trial, proceeding to well-matched UD HSCT at the time of failure of first immunosuppressive therapy is a reasonable choice for pediatric patients.[909] Alternative donor transplant as primary therapy for SAA in children is attractive, but, ideally, recommendations would result from a randomized trial so that robust data would illuminate whether the befits of early HSCT (fewer infections/fewer transfusions/decrease in graft rejection/less end organ toxicity) would outweigh subjecting the 30% of children who have durable response to immunosuppressive therapy to the risks for HSCT (early mortality/end organ damage/potential of significant GVHD).[910]

Congenital Bone Marrow Failure Syndromes. It is essential to exclude inherited causes for bone marrow failure particularly in the pediatric population. Such a diagnosis has a major impact on both therapy and outcome. Children with these syndromes rarely have a sustained response to immunosuppressive therapy and in general it should not be administered. HSCT provides the only curative approach for the bone marrow failure. Before transplant, associated abnormalities in the kidneys, liver, or lungs must be identified and the preparative regimen chosen in the context of the specific syndrome. Donor selection mandates the exclusion of the same disease in any RD; this can be complicated in those patients lacking a specific genetic marker. Virtually all patients with congenital bone marrow failure have an associated cancer predisposition syndrome. Although successful HSCT may abrogate the risk for secondary leukemia/myelodysplasia, the risk for solid tumors is unaffected or can even be increased owing to exposure to chemotherapy and/or radiation therapy in the preparative regimen and the insult of cGVHD. The most common of these syndromes are discussed next.

Fanconi Anemia/Dyskeratosis Congenita. Fanconi anemia is an autosomal recessive disorder clinically characterized by a highly variable physical phenotype, progressive marrow failure, and a marked propensity to develop AML and certain solid tumors (see Chapter 6). HSCT can be curative for the hematologic manifestations of Fanconi anemia, but early experience revealed excessive regimen-associated morbidity and mortality and in vitro studies confirmed hypersensitivity to alkylating agents and radiation.[911,912] Development of specialized conditioning regimens mostly employing low doses of both CY and radiation has spurred the application of HSCT as a treatment option, and results using HLA-identical sibling donors are excellent if performed early in life before the development of MDS or leukemia,[913,914] with 2-year DFS of as high as 95%.[915] In addition, the first reported transplant using UCB as a stem cell source was successfully undertaken for a child with Fanconi anemia using cells from an HLA-identical sibling.[141]

In contrast, the outcome using alternative donors had historically been very poor, with survival rates of approximately 30%[916-918]; graft failure and GVHD were the major causes of failure. The addition of fludarabine to the conditioning regimen and the removal of TBI have led to significant improvements in outcomes. In a recent review of patients with Fanconi anemia receiving UD, HSCT patients younger than 10 years old who had fewer than 20 transfusions and who received a fludarabine-containing regimen and T-cell–depleted marrow allografts had better outcomes, with 3-year survival of 52%.[919] Thus the prognosis for patients with Fanconi anemia receiving alternative-donor SCT has greatly improved over time and early referral for discussion of HSCT is indicated in patients with marrow failure.[920] There are limited data on the use of HSCT in patients with Fanconi anemia who have developed frank leukemia. Anecdotal reports suggest that there are occasionally long-term survivors, but death from regimen-related toxicity or leukemic relapse is frequent. A recent report from the Minnesota group on 21 patients with Fanconi anemia treated over the past two decades with HSCT for advanced MDS or acute leukemia reported a 5-year overall survival of 33%. Whether pre-HSCT chemotherapy adds more benefit than toxicity remains unclear.[921] Although HSCT can restore normal hematopoiesis, meticulous follow-up of these patients is essential because they retain a significant risk for developing solid tumors, particularly squamous cell carcinomas of the upper gastrointestinal tract and anogenital regions. The peak incidence occurs in the second and third decades of life. A European report on almost 800 patients with Fanconi anemia identified older age (>10 years) at time of HSCT, use of PBSCs, and the development of cGVHD as risk factors for secondary malignancy.[922] The outcome in patients developing these cancers is poor, so it is essential to try to decrease the incidence (through avoidance of radiation in the preparative regimen and prevention of cGVHD) and monitor patients closely so diagnosis can be made at an early stage of disease.[923,924]

Dyskeratosis congenita is a rare congenital bone marrow failure syndrome inherited in an autosomal dominant or recessive fashion. It is caused by changes in telomere biology and associated changes in chromosomal stability. The diagnostic criterion is the presence of extremely short (<1st percentile) telomere length in the lymphocyte population; two thirds of patients will also have an identifiable mutation in a gene affecting telomere function. The characteristic clinical findings are oral leukoplakia, nail dystrophy, and reticular pigmentation of the neck and upper chest. By age 30, more than 80% of patients exhibit signs of bone marrow failure and HSCT can restore normal hematopiesis. Dyskeratosis congenita is a disease of defective DNA repair, and although toxicity is not as severe as that seen in Fanconi anemia, patients have increased transplant-related toxicity when receiving full-dose conditioning. There is currently no standard approach, but the majority of patients in the modern era have received a combination including fludarabine and low-dose TBI. In 34 patients reported to the international registry, 5-year survival after HSCT was not quite 60%. Reduced-intensity regimens caused less acute toxicity but late deaths, the majority of which were from graft failure or pulmonary fibrosis assumed to be related to the underlying dyskeratosis congenita phenotype, remain a challenging problem.[925] The development of post-HSCT malignancies is not as common as in Fanconi anemia but still represents a major cause of morbidity and mortality. In an analysis of more than 500 patients with dyskeratosis congenita at the National Institutes of Health, the risk for cancer was elevenfold greater than that of the general population. The most common malignancies were squamous cell carcinomas of the head and neck, followed by skin and anorectal cancer.[926] Thus, as for all patients with congenital bone marrow failure syndromes, lifelong follow-up by specialists dedicated to the care of these rare diseases is mandatory.

Diamond-Blackfan Anemia. Diamond-Blackfan anemia is a rare, heritable condition manifesting as pure red cell aplasia due to an intrinsic erythroid progenitor defect. Approximately one third of patients have associated physical abnormalities, including short stature, cardiac or urogenital abnormalities, cleft palate, and microcephaly.[927] Haploinsufficiency of ribosomal protein S19 (RPS19) occurs in 20% to 25% of patients. Patients are generally diagnosed in the first months of life, presenting with anemia, macrocytosis, and reticulocytopenia (see Chapter 6). Although approximately two thirds of children initially respond to corticosteroid therapy, many fail to respond or lose response over time.[927] However, response to corticosteroids may wax and wane and 15% to 25% of children will attain a durable spontaneous remission, which makes it difficult to know when to pursue an intense intervention such as HSCT.[928] However, there can be significant toxicity associated with a conservative approach whether from sequelae of chronic transfusions or of prolonged corticosteroid use. Diamond-Blackfan anemia is a cancer predisposition syndrome, and patients are at risk for developing neoplasias in early to mid adulthood.[929] In the Diamond-Blackfan anemia registry the cumulative incidence of solid tumor/leukemia was 20% by age 46.[930] Allogeneic HSCT can offer a curative option when corticosteroids are no longer efficacious or associated with unacceptable toxicity. The first transplant was performed in 1976.[931] Children receiving transplants from matched sibling donors with a BU-based myeloablative regimen have historically done well, with EFS greater than 90%. Patients receiving alternative donor transplants fared poorly, with a 14% survival in early reports,[932] but outcomes are now approaching those seen in the sibling donor setting.[933] The Japanese Aplastic Anemia Registry reported a 100% 5-year survival in 13 patients with Diamond-Blackfan anemia receiving an allogeneic bone marrow transplant from either sibling donors or UDs; however, 3 of 3 patients receiving unrelated UCB transplants experienced graft failure.[934] Thus transplantation from a suitable bone marrow donor provides a reasonable option for those patients who fail to have a sustained response to medical therapy.[935]

GLOBAL HEALTH AND HEMATOPOIETIC STEM CELL TRANSPLANTATION

The field of HSCT has made impressive advances over the past 3 decades, particularly in the reduction of acute toxicity, through the use of less intense conditioning regimens and advances in supportive care. In addition, experience with alternative stem cell sources such as UCB facilitates donor identification for an increasingly diverse group of patients. Although HSCT was initially only performed in highly developed countries, the past decade has seen marked growth in the global application of transplant.

There is unquestionably a need for HSCT to be an available therapeutic option in the developing world, particularly for pediatric patients. The incidence of the major hemoglobinopathies is rising rapidly in the Middle East and Southeast Asia, and there is a critical lack of infrastructure for long-term provision of safe transfusion support, infection prevention, and iron overload management.[936] Lack of adequate supportive care also makes the curative approach of HSCT attractive in many of the other common nonmalignant transplantable conditions in children: bone marrow failure syndromes, immunodeficiency diseases, and storage diseases. In the malignant arena, there is difficulty and expense involved in procuring and administering lifelong TKI therapy in patients with CML and the intense (AML) or protracted (ALL) therapy needed for other hematologic malignancies raises the question of whether HSCT may be a preferable approach in the resource-poor setting if it could be done performed safely and effectively.

However, the obstacles to providing the intense, prolonged, and sophisticated care required to support a platform of HSCT cannot be understated. Although there is a greater probability of identifying a matched family donor in the Middle East than the United States, owing to larger family size and marriages between relatives,[937] it will be difficult to identify donors in the existing registries for those lacking a family donor given the underrepresentation of ethnic minority populations. UCB offers an attractive alternative because matching requirements are more permissive, but unrelated UCB units are expensive and the delayed engraftment and increased risk for graft rejection pose challenges. The technology necessary to maintain an acceptable cell processing facility is costly and requires specific expertise. Other problematic issues include having the consistent ability to provide sophisticated supportive care during the acute transplant period, including management of nutritional issues and pain, readily available transfusion support, and, most fundamentally, the provision of a guaranteed drug supply. Housing and social support must be available to families who may be away from home and work for prolonged periods. Infections must be expeditiously identified and appropriately treated. The incidence of infectious exposures varies between geographic regions and individual countries and is generally higher in the developing world. In Egypt, for example, 15% of the population has had prior exposure to hepatitis C, as manifested by antibody positivity, and 3% are positive for hepatitis B surface antigen. This impacts both donor availability and the risk for patient complications during transplant, including VOD and GVHD. There are also cultural differences impacting issues as diverse as allowing a sibling to donate marrow or choosing a therapy that impacts fertility, and transplant approaches must be viewed as part of a broader cultural context. Even if HSCT is successfully navigated, patients are at risk for long-term complications, particularly in the setting of cGVHD, that may be more significant than those associated with the primary disease for which transplant was performed.

There are currently major transplant centers in the Middle East, India, Southeast Asia, and South America, although there are still many individual countries in these areas without an HSCT program. The majority of centers limit activity to autologous and matched family donor transplants. Some financial data exist, and it appears unsurprisingly that once a transplant center is established the cost (in U.S. dollars) of individual procedures is relatively low—about $15,000 in India (2001) and Egypt (2008) and $50,000 in Chile (2008). Few centers report outcomes to international registries,[938] but published series show DFS of 50% to 80%,[939-941] indicating the possibility of cure for a subset of patients.

Future initiatives include developing geographic centers of excellence in central regional locations, perhaps with a focus on a limited number of diseases where the efficacy of HSCT is well understood. Collaborations with well-established centers can provide virtual and onsite training and ongoing support, including the development of a robust quality management program that will support programmatic improvements.[942] Finally, academic collaborations and publications must occur, because a well-functioning research infrastructure will enhance meticulous data collection, establish international credibility, and allow a presence at international meetings. Ultimately, the entire field of HSCT will benefit as global differences in epidemiology and genetics and differing approaches to supportive care practices inform ongoing advances in transplantation.

The decision of which children with acute leukemia in the modern era to undergo HSCT is complicated. This study and article clarifies the role of transplantation in select patients with acute myelogenous leukemias.

713. Leung W, Pui CH, Coustan-Smith E, et al: Detectable minimal residual disease before hematopoietic cell transplantation is prognostic but does not preclude cure for children with very-high-risk leukemia. *Blood* 120:468–472, 2012.

The presence of minimal residual disease is of increasing importance in the decision to go to transplant. This study outlines the key issues in the minimal residual disease discussion.

731. Millot F, Baruchel A, Guilhot J, et al: Imatinib is effective in children with previously untreated chronic myelogenous leukemia in early chronic phase: results of the French national phase IV trial. *J Clin Oncol* 29:2827–2832, 2011.

This is the largest study on the use of imatinib in pediatric patients presenting with chronic phase chronic myelogenous leukemia. This prospective trial showed excellent progression-free survival, similar to that reported in much larger series of adult patients, but a relatively high rate of drug cessation due to side effects.

761. Matthay KK, Villablanca JG, Seeger RC, et al: Treatment of high-risk neuroblastoma with intensive chemotherapy, radiotherapy, autologous bone marrow transplantation, and 13-*cis*-retinoic acid. Children's Cancer Group. *N Engl J Med* 341:1165–1173, 1999.

This is one of the few randomized trials in pediatric transplantation and shows the benefit of high-dose chemotherapy with autologous stem cell rescue in the treatment of advanced-stage neuroblastoma.

797. Walters MC, Patience M, Leisenring W, et al: Bone marrow transplantation for sickle cell disease. *N Engl J Med* 335:369–376, 1996.

This is the first report of a multiinstitutional trial demonstrating the efficacy of matched sibling donor bone marrow transplant in the treatment of children with sickle cell disease. Toxicity was acceptable and graft rejection rates low; stabilization of pulmonary and central nervous system disease was seen.

825. La Nasa G, Caocci G, Efficace F, et al: Long-term health-related quality of life evaluated more than 20 years after hematopoietic stem cell transplantation for thalassemia. *Blood* 122:2262–2270, 2013.

This is a seminal paper that demonstrates not only the curative potential of transplant in thalassemia but also the excellent quality of life enjoyed by survivors more than 20 years after transplant. Perhaps most intriguingly, an age/sex-matched cohort of patients receiving conventional therapy for thalassemia had poorer outcomes in terms of quality-of-life measures.

831. Mazzolari E, Forino C, Razza A, et al: A single-center experience in 20 patients with infantile malignant osteopetrosis. *Am J Hematol* 84:473–479, 2009.

This is one of the largest and most comprehensive reports on the genetics and phenotypic variation in patients with osteopetrosis.

850. Prasad VK, Mendizabal A, Parikh SH, et al: Unrelated donor umbilical cord blood transplantation for inherited metabolic disorders in 159 pediatric patients from a single center: influence of cellular composition of the graft on transplantation outcomes. *Blood* 112:2979–2989, 2008.

The size of the cohort in this group of patients with rare disorders and the expertise of the transplant center makes this essential reading for those interested in these challenging transplants.

865. Peters C, Charnas LR, Tan Y, et al: Cerebral X-linked adrenoleukodystrophy: the international hematopoietic cell transplantation experience from 1982 to 1999. *Blood* 104:881–888, 2004.

Adrenoleukodystrophy has unique features to other transplantable diseases but has aspects that apply to other neurodegenerative diseases. The key points of this article are important for adrenoleukodystrophy and multiple other inherited disorders.

885. Marsh RA, Vaughn G, Kim MO, et al: Reduced-intensity conditioning significantly improves survival of patients with hemophagocytic lymphohistiocytosis undergoing allogeneic hematopoietic cell transplantation. *Blood* 116:5824–5831, 2010.

A key element to the transplantation of children with hemophagocytic lymphohistiocytosis is the reduction of transplant related mortality and improvement in overall survival. Reduced-intensity conditioning is being investigated for this disease and may contribute to improved reduced-intensity mortality.

900. Eapen M, Ramsay NK, Mertens AC, et al: Late outcomes after bone marrow transplant for aplastic anaemia. *Br J Haematol* 111:754–760, 2000.

This single-institution case-controlled study examined late outcomes of children and young adults transplanted for aplastic anemia between 1975 and 1996. Validating the efficacy of transplant in this population, the authors found no significant difference in the self-rating of health status between patients and control subjects and an excellent level of social integration in survivors.

919. Wagner JE, Eapen M, MacMillan ML, et al: Unrelated donor bone marrow transplantation for the treatment of Fanconi anemia. *Blood* 109:2256–2262, 2007.

This retrospective registry report of 98 patients with Fanconi anemia undergoing unrelated donor transplantation highlights the improved survival with preparative regimens using fludarabine and T-cell depletion. Also, those transplanted at a younger age and with fewer transfusions fared better, emphasizing the advantage of expedient referral for transplant once marrow failure occurs.

926. Alter BP, Giri N, Savage SA, et al: Cancer in dyskeratosis congenita. *Blood* 113:6549–6557, 2009.

This retrospective review of all cases of dyskeratosis congenita published over the past 98 years highlights the markedly increased risk for cancer. Only patients with Fanconi anemia are at greater risk for developing a malignancy, and patient counseling and posttransplant monitoring should be similar in these two populations.

936. Weatherall DJ, Clegg JB: Thalassemia—a global public health problem. *Nat Med* 2:847–849, 1996.

This illuminating article reports on the uneven distribution of thalassemia births, with the majority now occurring in low- and middle-income countries. The lack of an infrastructure to provide lifelong care for transfusion-dependent patients in these settings raises the complex issue of how the curative approach of transplant could be best incorporated into the care of this population.

CHAPTER 9

Diagnostic Approach to the Anemic Patient

Carlo Brugnara, Frank A. Oski, and David G. Nathan

CHAPTER OUTLINE

INTRODUCTION
DEFINITION OF ANEMIA
CLASSIFICATION OF ANEMIAS
EVALUATION OF THE ANEMIC PATIENT
Initial Encounter
Selection of Appropriate Laboratory Tests
Automated Cell Counting
The Blood Film

INTRODUCTION

In this chapter we attempt to provide a useful guide to the rapid and accurate diagnosis of anemia in children and young adults. We do not dwell on each diagnosis because they are described in detail throughout the book.

Though productive methods of differential diagnosis of anemia vary greatly with the age of the pediatric patient, the most valuable tools at all ages remain the history and physical examination. Even in the neonate the history of the pregnancy, the family history, and the events surrounding birth are paramount, and the appearance of the newborn baby strongly influences diagnosis. In fact, the history and physical examination may well be more useful than examination of the blood because the morphology of the red cells of normal neonates may be strikingly abnormal. Morphology of neonatal blood can be very deceiving. As mentioned below, anemia is due to either hemorrhage, failure of erythropoiesis, accelerated hemolysis, or combinations of the three. The symptoms of anemia are well established. They are due either to sudden blood volume loss or to chronic redistribution of a low blood volume with a high fraction sequestered in the central blood volume, both complicated by low oxygen carrying capacity. The results are weakness, dyspnea and fatigue, cold intolerance, dizziness, and depression. If the blood volume loss is substantial and sudden, the patient may present in a state of collapse. If anemia develops slowly, low oxygen carrying capacity may be compensated by a higher cardiac output due to the rise in central blood volume and a lowering of blood viscosity and by increased erythrocyte 2,3-DPG. In fact, patients with slowly developing anemia to as low as 1 g of hemoglobin (Hb) per 100 mL of blood have been observed to walk into clinics. But this is surely a feat of the young. Older patients with less accommodating vascular trees are not capable of such gymnastics. Woe to such a patient who encounters a physician determined to transfuse with red cells without removing an equal volume of watery blood. The maneuver will surely drive the victim's massively expanded central blood volume into pulmonary edema.

The rate of development of symptoms provides strong etiologic clues because the normal red cell life span is 3.5 months, and cardiac compensation for a falling oxygen carrying capacity can blunt symptoms. Thus a patient who suddenly complains of severe fatigue and is noticeably pale has probably lost red cells rapidly. This must be due to hemolysis or bleeding. If the symptoms accumulate slowly, this is likely due to failure of erythropoiesis that may be complicated by malnutrition, endocrine deficiencies such as thyroid or adrenal failure, and/or by renal insufficiency or inflammatory disease with concomitant inhibition of iron absorption.

The physical examination of the anemic patient may be particularly revealing of etiology. Pallor is nonspecific, but when tinged with jaundice, it may suggest increased hemolysis. This is readily confirmed if the foam of shaken urine remains white. Yellow skin or sclera without biliuria strongly indicates that the circulating bilirubin has NOT been conjugated and is the direct product of rapidly hemolyzed red cells. Indeed, in the absence of liver disease, the level of unconjugated bilirubin in the peripheral blood is a direct function of red cell turnover. The relationship is confusing in the neonate because of its physiologic defect in the conjugation pathway and is not accurate in liver disease.

Examination of the tongue and oral mucosa will reveal vitamin, iron, and corticosteroid deficiencies, while stature and the skeleton, particularly the forehead, face, and skull, may indicate the chronicity of hemolysis and concomitant energy consumption and marrow space expansion. The digits may reveal boney abnormalities seen in congenital anemias. Enlarged lymph nodes and their texture, together with hepatosplenomegaly, may suggest invasive or infectious diseases, as do petechiae or other skin lesions. The pulse rate and blood pressure and the heave of the heart against the chest may reveal the length and severity of anemia, while the lungs may demonstrate the incipiency of pulmonary edema. A walk up the stairs with comparison of patient and caretaker pulse rates may be highly revealing. Neurologic examination may show the characteristic slow return of Achilles tendon reflexes seen in hypothyroidism or the posterior column defects of vitamin B_{12} deficiency.

DEFINITION OF ANEMIA

Anemia is generally defined as a reduction in red cell mass or blood Hb concentration. The limit for differentiating anemic from normal states is usually set at 2 standard deviations below the mean for the normal population. This definition will result in 2.5% of the normal population being classified as anemic. Conversely, values for Hb-deficient individuals are distributed in such a fashion that some are placed within the normal range. These individuals, who have the potential for an Hb concentration in the upper part of the normal range, may be recognized only after a response to treatment. Definition of the lower limit of normal for both pediatric and adult patients is critically dependent on the population used to establish the normal range of values.[1] Hematocrit (Hct), Hb, and mean corpuscular volume (MCV) are significantly lower in African Americans than in Caucasians. A third of this difference can be accounted for by the α-globin 3.7 kb deletion.[2] In the absence of a race-specific normal range, the fact that African Americans generally have lower Hb levels than Caucasians (approximately 0.5 g/dL) could result in 10% of normal African-American children being considered anemic just because the proper normal range is not used.[3,4] Figure 9-1 presents pediatric reference ranges for Hb in Caucasians, African Americans, and Mexican Americans that were obtained from the National Health and Nutrition Examination Survey (NHANES) III database.

Because the primary function of the red cell is to deliver and release adequate quantities of oxygen to tissues to meet their metabolic demands, it is apparent that some measures of both body oxygen metabolism and accompanying cardiovascular compensation are required to complement the current laboratory definition of anemia. The fact that Hb concentration alone is insufficient to judge whether a patient is "functionally anemic" is best illustrated in a patient with cyanotic congenital heart disease or chronic respiratory insufficiency or in one with mutant Hbs that alter Hb's affinity for oxygen (see Chapter 19).

With these caveats in mind, a useful statistical definition of anemia that recognizes the effect of age, gender, and ethnicity on the designation of anemia is provided in Figure 9-2.[5,6]

CLASSIFICATION OF ANEMIAS

Anemias may be classified on the basis of physiology or morphology. A combination of both approaches is often used in the initial differential diagnosis.

To determine and distinguish the multiple disorders capable of producing anemia, one must separate the causes of anemia into two categories of functional disturbances:

1. Disorders of effective red cell production, in which the net rate of red cell production is depressed. This can be due to disorders of erythrocyte maturation, in which erythropoiesis is present but ineffective, or to an absolute failure of erythropoiesis. In the former the bone marrow may contain many erythroblasts that die in situ before reaching the reticulocyte stage. In the latter there is absolute erythroblastopenia.
2. Disorders in which rapid erythrocyte destruction or red cell loss is primarily responsible for the anemia.

These two categories are not mutually exclusive. More than one mechanism may be present in some anemias, but one functional disorder is generally the major reason for the patient's anemia. Box 9-1 lists the anemias most commonly encountered in infancy and childhood and classifies them into three categories of functional disturbance.

Anemias may also be classified on the basis of red cell size and then further subdivided according to red cell morphology. In this type of classification, anemias are subdivided into microcytic, normocytic, and macrocytic anemias. This classification is also arbitrary, and categories are not mutually exclusive. For example macrocytic reticulocytes abound in the hemolytic anemias. Therefore, although mature erythrocytes in the various hemolytic anemias may be normocytic, the MCV of all the cells may be larger than normal because of the contribution of reticulocytes to the volume measurement.[7] Volume distribution curves may reveal the contribution of a subset of large cells to the MCV. Furthermore, during the course of a disease, classification of the patient's anemia may change from one category to another as a result of other clinical or pathologic variables. In Box 9-2 the more common anemias of infancy and childhood are classified on the basis of their characteristic cell size.

EVALUATION OF THE ANEMIC PATIENT

Initial Encounter

The initial diagnostic approach to an anemic patient includes a detailed history and physical examination and

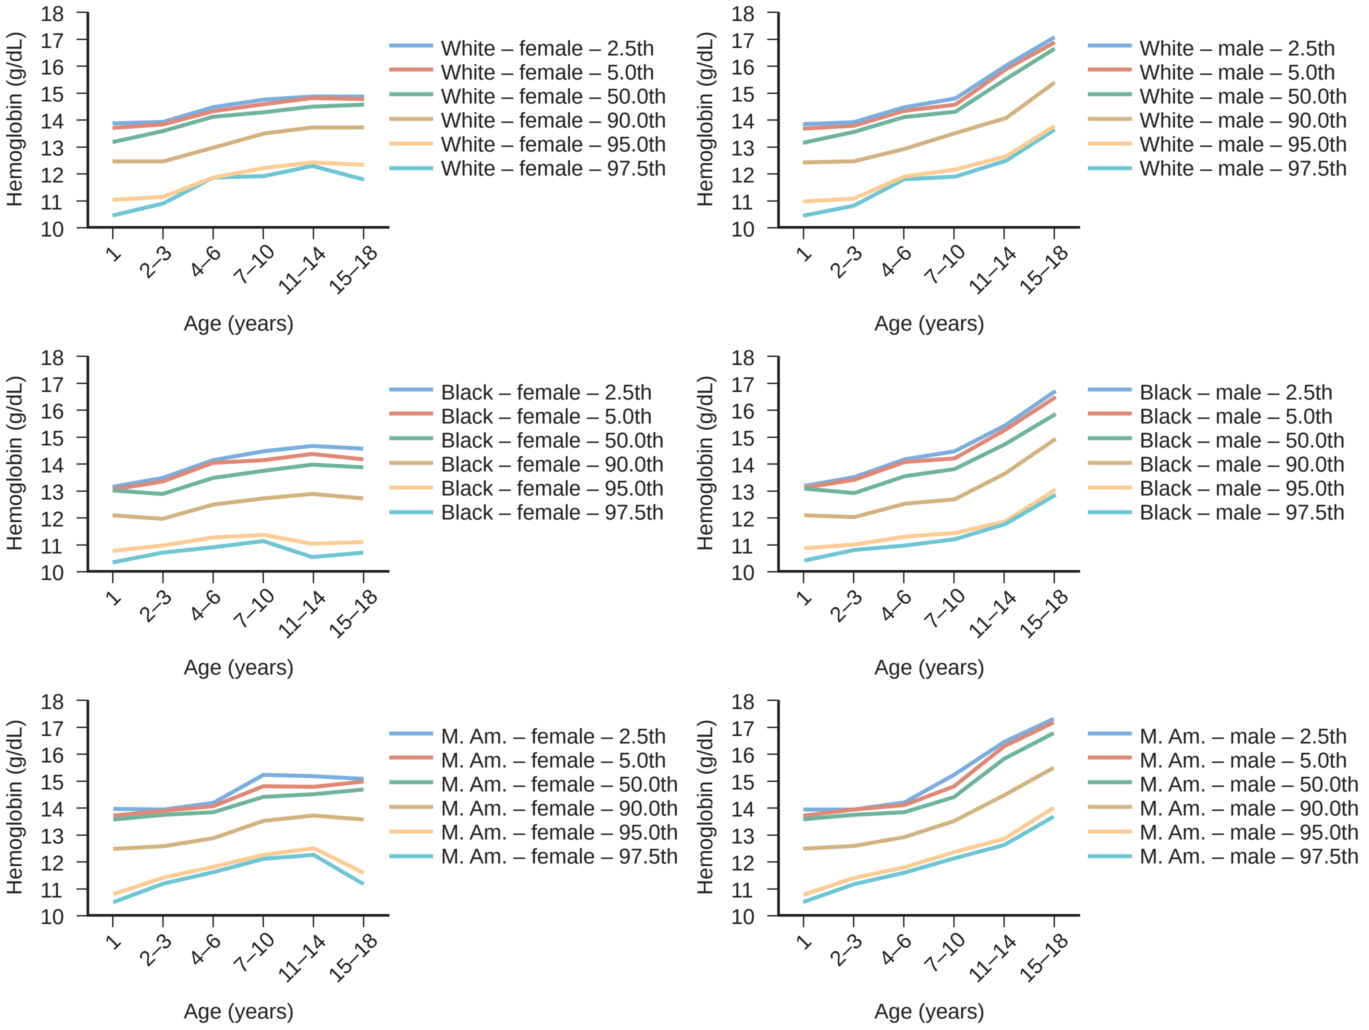

Figure 9-1 Pediatric reference ranges for hemoglobin in Caucasions *(top row)*, African Americans *(middle row)*, and Mexican Americans *(bottom row)*. *(From Cembrowski GS, Chan J, Cheng C, Bamforth FJ: NHANES 1999-2000 data used to create comprehensive health-associated race-, sex- and age-stratified pediatric reference intervals for the Coulter MAXM.* Lab Hematol *10:245–246, 2004. Presented at the annual meeting of the International Society for Laboratory Hematology, Barcelona, Spain, May 2004. Numerical summary provided by GS Cembrowski, MS Cembrowski, KA Versluys, 2013. See Appendices 13 to 14 for complete data sets.)*

a minimum of essential laboratory tests. Box 9-3 and Table 9-1 list the features of the history and physical examination that are most helpful in providing clues to the cause of the anemia. Often they may be more diagnostic than the laboratory studies.

Family History: Because the prevalence of hemoglobinopathies and thalassemias varies greatly among different ethnic backgrounds, it is important to inquire about ethnicity. A family history of anemias or symptoms that may be related to anemias, like jaundice, gallstones, cholecystectomy/splenectomy, and transfusion, in family members should be investigated. A family history of blood loss (menorrhagia, epistaxis) may suggest that the anemia is due to the presence of an inherited bleeding disorder.

Personal History: With almost universal newborn screening in the United States and other developed countries, many patient encounters are generated by the identification of a hemoglobinopathy by newborn screening in the absence of any symptomatology. For all other circumstances, the history should focus on the characterization of possible hemolytic crises or episodes of blood loss. Menstrual history should be obtained in all girls. If the patient has recently moved from or traveled to an underdeveloped country, intestinal parasite infestation (hookworm, whipworm) should be considered, as well as malaria and infectious hepatitis. A dietary history is crucial to identify conditions favoring folate deficiency or iron deficiency. A detailed medication history is of great importance to identify drugs that may directly produce anemia or may be contributing to anemia via increased blood losses (e.g., aspirin, nonsteroidal antiinflammatory drugs).

Physical Examination: The presence of congenital defects is an important feature of congenital anemias, such as Fanconi's anemia (FA). Skeletal abnormalities (hypoplastic or absent thumb/radius) are present in at least half of patients with FA. Many of these patients also have short stature.

Box 9-1 **Physiologic Classification of Anemia**

1. Disorders of red cell production in which the rate of red cell production is less than expected for the degree of anemia
   a. Marrow failure
      - Aplastic anemia
        Congenital
        Acquired
      - Pure red cell aplasia
        Congenital
          Diamond-Blackfan syndrome
          Aase's syndrome
        Acquired
          Transient erythroblastopenia of childhood
          Human parvovirus B19 infection
      - Marrow replacement
        Malignancies
        Osteopetrosis
        Myelofibrosis
        Chronic renal disease
        Vitamin D deficiency
        Granulomatous infection
      - Pancreatic insufficiency–marrow hypoplasia syndrome
      - Fanconi's anemia
   b. Impaired erythropoietin production
      - Chronic renal disease
      - Hypothyroidism, hypopituitarism
      - Chronic inflammation
      - Protein malnutrition
      - Hemoglobin mutants with decreased affinity for oxygen
   c. Anemia of chronic disease
2. Disorders of erythroid maturation and ineffective erythropoiesis
   a. Abnormalities in cytoplasmic maturation
      - Iron deficiency
      - Thalassemia syndromes
      - Sideroblastic anemias
      - Lead poisoning
   b. Abnormalities in nuclear maturation
      - Vitamin B_{12} deficiency
      - Folic acid deficiency
      - Thiamine-responsive megaloblastic anemia
      - Hereditary abnormalities in folate metabolism
      - Orotic aciduria
      - Zinc-induced copper deficiency
   c. Congenital dyserythropoietic anemias (types I, II, III, IV)
   d. Erythropoietic protoporphyria
   e. Refractory sideroblastic anemia with vacuolization of marrow precursors and pancreatic dysfunction/deficiency
3. Hemolytic anemias
   a. Defects in hemoglobin
      - Structural mutants
      - Synthetic mutants (thalassemia syndromes)
   b. Defects in the red cell membrane
   c. Defects in red cell metabolism
   d. Antibody mediated
   e. Mechanical injury to the erythrocyte
   f. Thermal injury to the erythrocyte
   g. Oxidant-induced red cell injury
   h. Infectious agent–induced red cell injury
   i. Paroxysmal nocturnal hemoglobinuria
   j. Plasma lipid–induced abnormalities in the red cell membrane

Box 9-2 Classification of Anemias Based on Red Cell Size

MICROCYTIC ANEMIAS

Iron deficiency (nutritional, chronic blood loss)
Chronic lead poisoning
Thalassemia syndromes
Sideroblastic anemias
Chronic inflammation
Some congenital hemolytic anemias with unstable hemoglobin

MACROCYTIC ANEMIAS

- With megaloblastic bone marrow
  - Vitamin B_{12} deficiency
  - Folic acid deficiency
  - Hereditary orotic aciduria
  - Thiamine-responsive anemia
- Without megaloblastic bone marrow
  - Aplastic anemia
  - Diamond-Blackfan syndrome
  - Hypothyroidism
  - Liver disease
  - Bone marrow infiltration
  - Dyserythropoietic anemias

NORMOCYTIC ANEMIAS

- Congenital hemolytic anemias
  - Hemoglobin mutants
  - Red cell enzyme defects
  - Disorders of the red cell membrane
- Acquired hemolytic anemias
  - Antibody mediated
  - Microangiopathic hemolytic anemias
  - Secondary to acute infections
- Acute blood loss
- Splenic pooling
- Chronic renal disease (usually)

There is substantial variability in the effectiveness of the compensatory mechanisms for anemia: While in some cases the severity of the anemia is evident based on the presence of tachycardia, lethargy, or pallor, in other cases a very severe, chronic anemia may be associated with a paucity of symptoms. Short stature and skeletal changes induced by expansion of the erythroid mass should also be noted because they are often the result of anemia and expansion of erythroid marrow.

Selection of Appropriate Laboratory Tests (Box 9-4)

First-Tier Tests

- The initial laboratory tests should always include a complete blood count (CBC) with white blood cell differential, a reticulocyte count, and an examination of a peripheral blood smear. If a test for the identification of Hb variants is included in this initial panel, high-performance liquid chromatography, capillary electrophoresis, or isoelectrofocusing should be preferred over classic cellulose acetate and acid-citrate Hb electrophoresis. A glucose-6-phosphate dehydrogenase screening test, total and direct bilirubin, lactate dehydrogenase (LDH), and iron studies (serum iron, total iron binding capacity, and ferritin concentrations) should also be considered as part of the initial laboratory evaluation of the anemic child. It should be noted that LDH is not a marker of hemolysis: Elevated LDH is an indication of *intravascular* hemolysis. With reliable clinical grade assays now in place, serum hepcidin might be included if iron deficiency is unexplained.[8,9]

Box 9-3 Historical Factors of Importance in Evaluating Patients with Anemia

AGE

Nutritional iron deficiency is never responsible for anemia in term infants before 6 months of age and rarely seen in premature infants before the time that they have doubled their birth weight. Anemia occurring in the neonatal period is generally the result of recent blood loss, isoimmunization, or initial manifestation of a congenital hemolytic anemia or congenital infection. Anemia first detected at 3 to 6 months of age suggests a congenital disorder of hemoglobin synthesis or hemoglobin structure.

GENDER

Consider X-linked disorders in males (G6PD deficiency, pyruvate kinase deficiency).

RACE

Hemoglobins S and C more common in African Americans; β-thalassemia more common in Caucasians; α-thalassemia trait most common among African Americans and Asians

ETHNICITY

Thalassemia syndromes most common among patients of Mediterranean origin. G6PD deficiency observed more often among Sephardic Jews, Filipinos, Greeks, Sardinians, and Kurds

NEONATAL

A history of hyperbilirubinemia in the newborn period suggests the presence of congenital hemolytic anemia, such as the hereditary spherocytosis of G6PD deficiency. Prematurity predisposes to the early development of iron deficiency.

DIET

Document sources of iron, vitamin B_{12}, folic acid, or vitamin E in the diet. A history of pica, geophagia, or pagophagia suggests the presence of iron deficiency.

DRUGS

Oxidant-induced hemolytic anemia, phenytoin (Dilantin)-induced megaloblastic anemia, drug-induced aplastic anemia

INFECTION

Hepatitis-induced aplastic anemia, infection-induced red cell aplasia, hemolytic anemia

INHERITANCE

Family history of anemia, jaundice, gallstones, or splenomegaly

DIARRHEA

Suspect small bowel disease with malabsorption of folate or vitamin B_{12}. Suspect inflammatory bowel disease with blood loss. Suspect protein-losing enteropathy with blood loss.

G6PD, Glucose-6-phosphate dehydrogenase.

Second-Tier Tests

- Based on the initial evaluation of the patient and the first round of laboratory tests, additional disease-specific tests should be considered. In the presence of macrocytosis, plasma B_{12}, folate, and perhaps homocystein and serum/urine methylmalonic acid should be determined together with a measurement of thyroid hormone function. Osmotic fragility (nonincubated and incubated)

TABLE 9-1 Physical Findings as Clues to the Cause of Anemia

	Finding	Cause
Skin	Hyperpigmentation	Fanconi's aplastic anemia
	Petechiae, purpura	Autoimmune hemolytic anemia with thrombocytopenia, hemolytic-uremic syndrome, bone marrow aplasia, bone marrow infiltration
	Carotenemia	Suspect iron deficiency in infants
	Jaundice	Hemolytic anemia, hepatitis, aplastic anemia
	Cavernous hemangioma	Microangiopathic hemolytic anemia
	Ulcers on lower extremities	S and C hemoglobinopathies, thalassemia
Facies	Frontal bossing, prominence of the malar and maxillary bones	Congenital hemolytic anemias, thalassemia major, severe iron deficiency
Eyes	Microcornea	Fanconi's aplastic anemia
	Tortuosity of the conjunctival and retinal vessels	S and C hemoglobinopathies
	Microaneurysms of the retinal vessels	S and C hemoglobinopathies
	Cataracts	Glucose-6-phosphate dehydrogenase deficiency, galactosemia with hemolytic anemia in the newborn period
	Vitreous hemorrhages	S hemoglobinopathy
	Retinal hemorrhages	Chronic, severe anemia
	Edema of the eyelids	Infectious mononucleosis, exudative enteropathy with iron deficiency, renal failure
	Blindness	Osteopetrosis
Mouth	Glossitis	Vitamin B_{12} deficiency, iron deficiency
	Angular stomatitis	Iron deficiency
Chest	Unilateral absence of the pectoral muscles	Poland's syndrome (increased incidence of leukemia)
	Shield chest	Diamond-Blackfan syndrome
Hands	Triphalangeal thumbs	Red cell aplasia
	Hypoplasia of the thenar eminence	Fanconi's aplastic anemia
	Spoon nails	Iron defiency
Spleen	Enlargement	Congenital hemolytic anemia, leukemia, lymphoma, acute infection, portal hypertension

should be considered in the presence of possible hereditary spherocytosis (HS)/xerocytosis, although the presence of cells with high mean corpuscular Hb concentration (MCHC) is usually diagnostic of HS in the absence of hemoglobinopathy-induced cation loss, antibody-induced hemolysis, hereditary xerocytosis, and transient-hypoproliferative states. Serum haptoglobin, serum/plasma Hb, and urine hemosiderin should be considered in working up possible chronic hemolytic conditions as well as a direct and indirect antiglobulin test or Coombs test and red-cell or white-cell based flow cytometric assays for paroxysmal nocturnal hemoglobinuria (PNH).

- Supravital staining of erythrocytes (crystal violet to detect Heinz bodies or denatured Hb, brilliant cresyl blue for unstable Hb), a screening test for the presence of unstable hemoglobins like heat or isopropanol stability, should be considered if there are indications of possible unstable hemoglobinopathy or oxidant-induced hemolysis.
- Erythrocyte protoporphyrin is of limited value in the diagnosis of iron deficiency or lead poisoning. However, increased levels of erythrocyte protoporphyrin help to distiguish X-linked sideroblastic anemia type A (XLSA/A) due to deficiency in either ABCB7, SLC19A2, or other mitochondrial defects from classic XLSA due to ALAS2 mutations, which characteristically has low or normal levels.[10]

Box 9-4 Laboratory Investigation of Anemia

INITIAL STUDIES

Complete blood count with differential, reticulocyte count, and peripheral smear review
Hemoglobin variants identification (high-performance liquid chromatography or isoelectric focusing preferred)
Iron studies: Serum iron, serum transferrin, serum ferritin
Hemolysis indicators: Bilirubin (total and direct), serum lactate dehydrogenase (for intravascular hemolysis)
Glucose-6-phosphate dehydrogenase deficiency screening test

SECOND-TIER

Serum B_{12}, folate, red cell folate, and serum/urine methylmalonic acid
Osmotic fragility
Serum haptoglobin, serum/plasma hemoglobin, urine hemosiderin
Direct antiglobulin test and indirect antiglobulin test
Unstable hemoglobin screen (isopropanol or thermal stability), Heinz bodies prep
Paroxysmal nocturnal hemogloburinemia testing by flow cytometry (red blood cell and white blood cell)
Erythrocyte adenosine deaminase activity
Human parvovirus B19: Immunoglobulin M and G serum titers, viral DNA detection tests
Serum erythropoietin
Serum α-fetoprotein, mitomycin, or diepoxybutane test
Acid serum lysis test with ABO-compatible serum

THIRD-TIER

Bone marrow aspirate/biopsy
Electron microscopy
Complementation test (Fanconi's anemia subtyping)
Molecular genetic studies (congenital dyserythropoietic anemia types I and II, Blackfan-Diamond, and others)

- Erythrocyte adenosine deaminase, serum α-fetoprotein, mitomycin, or diepoxybutane tests are indicated for Diamond-Blackfan anemia (DBA) and FA, respectively.
- Family studies are helpful in the presence of challenging combinations of hemoglobinopathies/thalassemias and in HS/xerocytosis. Specialized red blood cell (RBC) enzyme studies should be considered with the caveat that only a handful of reference laboratories in the United States offer functional studies for red cell enzymopathies.
- To diagnose erythroid suppression induced by human parvovirus B19 infection, immunoglobulin M (IgM) and immunoglobulin G (IgG) serum titers and viral DNA detection tests should be considered.
- Serum erythropoietin (EPO) levels are indicated only when there is a question of inappropriately low EPO for the degree of anemia, provided that the laboratory has generated an EPO normal range as a function of Hct/Hb values.

Third-Tier Tests

- Bone marrow studies should be performed when there is clear evidence of a hypoproliferative anemia, except for cases of transient virus-induced erthroblastopenia, in which they are not indicated. Bone marrow studies are required to diagnose the presence of ringed sideroblasts, which are a distinguishing sign of sideroblastic anemias, to identify megaloblastic erythropoiesis and when there is a suspicion of an associated hematologic malignancy based on peripheral blood morphology.
- DNA-based diagnosis: Ordering of molecular studies should be the result of a proper balancing between the curiosity of the physician and the needs and possible benefits for the patient. Cost of these tests should also be considered, and whether they are associated with significant cost borne by the patient or family or by insurance carriers. For most of red cell membrane and red cell enzyme disorders, molecular testing rarely results in measurable benefits for the patients and their families and for the clinical management of the disease. Genetic testing has a value in congenital dyserythropoietic anemias (CDAs) and in DBA.

After the laboratory tests have been performed, the results may be used in an initial attempt to diagnostically characterize the patient's anemia, as illustrated by the simple algorithm in Figure 9-3. This algorithm provides additional diagnostic steps after the initial characterization of anemia based on the CBC, reticulocyte count, and cellular indices.

The most common cause of rapid red cell loss with reticulocytosis is hemorrhage. In infants and children, unusual causes include hemorrhage beneath the scalp and intraabdominal, urinary tract, and pulmonary hemorrhage. In the latter two situations, hyperbilirubinemia is not present. Indeed, if the hemorrhage is chronic and leads to iron deficiency, the plasma will be pale.

Sequestration in an abnormal spleen will usually cause spherocytosis, but if the hypersplenism is associated with liver disease, target cells will also be present. In this condition the osmotic fragility test will reveal a sensitive and a resistant population of erythrocytes.

Vascular damage to erythrocytes may be associated with thrombocytopenia and can be caused by hemangiomas (Kasabach-Merritt syndrome); intravascular coagulation, often secondary to sepsis; damaged artificial heart valves; and renal vascular disease and severe hypertension. Schistocytes, which resemble military helmets of various nationalities, are usually present, and siderinuria and hemoglobinuria are often detected.

Abnormalities in plasma are frequent causes of hemolysis. Antibodies usually induce spherocytosis by causing splenic sequestration, but sometimes they merely fix complement and cause hemoglobinuria without morphologic change. Many drugs and toxins can damage red cells either by oxidant injury with resultant schistocytosis or by direct lysis, as illustrated by bacterial lipases in septic shock or inoculation of venoms. Acute hemolysis may also be caused by excessive release of hepatic copper in Wilson's disease. No morphologic change is noted.

Primary membrane abnormalities that cause hemolysis are usually congenital and are associated with specific morphologic changes. An exception is PNH, which is an acquired membrane defect associated with no morphologic change. The congenital membrane defects are usually due to abnormalities in structural membrane proteins, such as in HS, but they may involve cation channels (hydrocytosis and xerocytosis) and, rarely, membrane lipids (abetalipoproteinemia).

When the bone marrow fails, as in many hypoproliferative anemias, the red cell volume is frequently increased above 100 fL, in conjunction with an increase in fetal Hb above 2%. Macrocytosis on the peripheral smear may be accompanied by neutropenia or thrombocytopenia or both.

Automated Cell Counting

The classic work of M.M. Wintrobe in 1930-1934 established the criteria for anemia classification based on cellular indices.[11-13] This approach is still in use today. In less than a minute, automated hematology analyzers provide a full CBC with measurements of MCV, MCHC, which also include estimates of the heterogeneity in the distributions of these parameters (red cell distribution width [RDW] for MCV and Hb distribution width [HDW] for MCHC). In automated cell counters using the electrical impedance principle (Abbott, Abbott Park, Ill.; ABX, Kyoto, Japan; Beckman-Coulter, Miami, Fla.; Sysmex, Kobe, Japan), cells passing through an aperture cause changes in electrical resistance that are counted as voltage pulses, which are proportional to cell volume. The electrical pulses are amplified and counted during the time that an accurately metered volume of the suspension is drawn through the aperture. These devices can directly measure MCV and compute the Hct from the MCV and red blood cell count.

Solutions, Tarrytown, N.Y.), single cells passing through a laser beam induce scattering of laser light, which can be detected and translated into measurements of cell size. In the instruments produced by Siemens, red cells first undergo isovolumetric sphering, and then MCV and the MCHC are measured from the low-angle forward light scattering and the high-angle (refractive index) light scattering, respectively.[14-16]

Some of the potential errors that can be generated by automated cell counters for Hb, Hct, and red cell indices are listed in Box 9-5.[17] Different Hct values can be obtained on the same sample simply due to the fact that MCV is measured with different technologies. Impedance-based instruments overestimate MCV in erythrocytes with increased MCHC and underestimate it in hypochromic erythrocytes. An artifactually low Hct can be obtained in impedance-based systems for samples containing significant quantities of hypochromic cells, leading to overestimation of anemia in conditions like anemia of chronic disease or chronic renal failure. Therefore Hb should be used instead of Hct to define anemia, because the former is an extremely reliable parameter in all types of analyzers. Although RDW is widely understood to represent the coefficient of variation for the distribution of MCV in a given blood sample, some analyzers calculate RDW from the width of this distribution, resulting in different normal range for this parameter. MCH is the only erythrocyte cellular parameter that is reliable across various analytical platforms because it is derived from direct and precise measurements of Hb and red cell count. Hematologists should train themselves to focus on that parameter instead of MCV, and distributions around MCH should be made available on analyzers. Table 9-2 provides a list of the red cell and reticulocyte parameters provided by the major hematology analyzers.

Cold agglutinins in high titer tend to cause spurious macrocytosis with low red cell counts and very high MCHCs. Warming either the blood or the diluent may eliminate this problem. In hyperglycemic samples (greater than 20 mmol/L), flow cytometric methods provide

Box 9-5 Sources of Spurious Results in Hemoglobin and Red Cell Count Parameters

ERRONEOUS INCREASE IN Hb

Lipemia (hypertriglyceridemia, fat emulsion, type I and IV hyperlipoproteinemias)
Elevated WBC counts (threshold varies from 50 to 250 × 10^9/L)
Immunoglobulins (monoclonal IgG, IgM, IgA in Waldenström's or multiple myeloma)
Hemolysis (when free plasma Hb is markedly elevated because of intravascular hemolysis)

ERRONEOUS INCREASE IN RBC COUNTS

High WBC count (especially if greater than 100 × 10^9/L)

ERRONEOUS INCREASE IN MCV

Hyperglycemia (secondary to dilution of a severe hyperglycemic sample)
Hypernatremia
Sample storage at room temperature

ERRONEOUS DECREASE IN RBC COUNTS

Cold agglutinin (in association with high MCV and high MCHC)
Clotting (abnormal mixing, overfilling of sample)

falsely elevated MCV and Hct and inaccurately low MCHC values. This is the result of cell swelling produced when the instrument dilutes the blood sample with a diluent that is not isotonic compared with the hyperglycemic sample.[18]

The classification based on MCV and RDW suggested by Bessman and associates[19] should not be used because it is an oversimplification that has been shown to be limited in its diagnostic yield and erroneous in several conditions. Contrary to what is suggested in this classification schema, a normal RDW can be seen in iron-deficient anemia, and increased RDW in α- and β-thalassemia traits. RDW changes are usually confirmative of a specific diagnosis obtained with other means, but they should

not be used for a primary diagnosis in the absence of other data.

Visual analysis of the red cell histograms generated by automated cell counters provides essential clues for the diagnosis of anemias. The presence of either microcytes or macrocytes and increased RDW can readily be appreciated. Even red cell fragments can now be precisely quantified.[20,21] Histograms for MCHC are particularly useful because they allow prompt identification of dehydrated hyperchromic cells in sickle cell disease, HS, hereditary xerocytosis, and immune hemolytic anemias. A plethora of discriminant functions has been proposed to distinguish β-thalassemia trait and iron deficiency, resulting in numerous and conflicting publications.[22] The Mentzer index (MCV/RBC) is still widely used, but it is inferior to some of the more modern parameters generated by automated cell counters. A more contemporary approach should take into account MCHC and HDW as shown in Figure 9-4.[23] A careful study of volume and Hb concentration histograms allows rapid differentiation of iron deficiency and β-thalassemia trait. But inspection of a well-stained smear provides the most reliable assay because morphology is considerably more abnormal at higher Hb levels in β-thalassemia trait than in iron deficiency. The plasma is very watery instead of yellow in iron deficiency, probably due to low levels of plasma Hb. Wintrobe pointed that out decades ago. Unfortunately the color of the plasma is no longer available to physicians or technicians.

Because MCV and MCHC are the average value obtained from counting large numbers of red cells, changes in red cell subpopulations may not result in changes in these average values: Hydroxyurea treatment of patients with sickle cell disease results in macrocytosis and increased MCH. However, due to the fact that both reticulocyte (low MCHC) and irreversibly sickle cells (high MCHC) are reduced by this treatment, MCHC may show little or no variation, while its distribution width (HDW) shows a significant decrease. Hyperchromic cells are a distinguishing characteristic of HS. In the absence of hemoglobinopathies like sickle Hb (Hb S) or Hb C, or autoimmune or traumatic hemolysis, presence of hyperchromic cells is diagnostic for HS, without the need of performing additional tests like osmotic fragility or more sophisticated flow cytometry studies. In sickle cell anemia the presence of dense dehydrated red cells (measured with a phthalate density gradients) seems to be associated with specific manifestations of the disease like skin ulcers, priapism, or renal dysfunction.[24] An increase in the proportion of dense hyperchromic cells can be seen in conditions of suppression of erythropoiesis: The reduction in the output of newly produced erythrocytes results in a shift in the distribution of the circulating red cells toward an "older" red cell population. A population in which older red cells prevail over younger ones is characterized by an increase in the proportion of hyperchromic cells and an increased in glycated Hb (Hb A_{1c}). This is typically seen when erythropoiesis is suppressed by viral infections or chemotherapy.

Microspherocytes and increased osmotic fragility are frequently seen in congenital dyserythropoietic anemia type II (CDAII), a chronic hemolytic disorder that can be confused with HS. CDAII is characterized by more prominent anisocytosis (increased RDW), while anisochromia (increased HDW) is more prevalent in HS; a RDW/HDW ratio greater than 5.34 has 89% sensitivity and 70% specificity to distinguish CDAII from HS.[25]

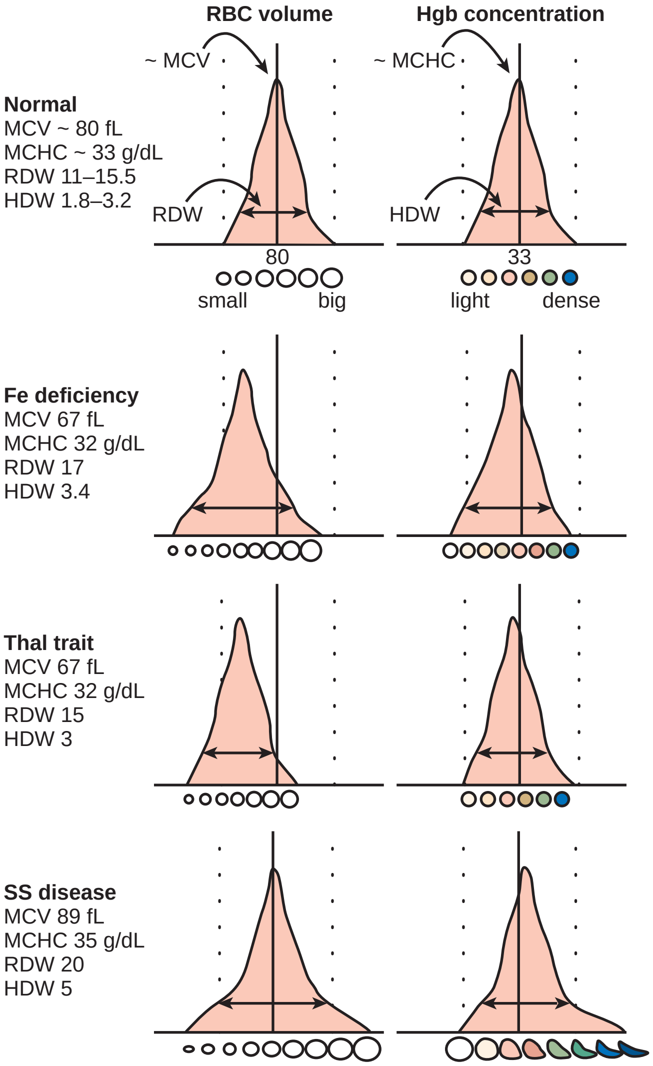

Figure 9-4 Histograms for mean corpuscular volume (MCV, *left column*) and mean corpuscular hemoglobin concentration (MCHC, *right column*) in a normal control subject *(first row)*, a patient with iron (Fe) deficiency *(second row)*, a subject with heterozygous β-thalassemia (Thal) *(third row)*, and a patient with homozygous hemoglobin S (SS) disease *(bottom row)*. Goal posts are placed at 60 and 120 fL for MCV and at 28 and 41 g/dL for MCHC. *HDW,* Hemoglobin distribution width; *Hgb,* hemoglobin; *RBC,* red blood cell; *RDW,* red cell volume distribution width.

Recent work has substantially expanded our understanding of how cell volume, cell Hb content, and concentration are dynamically linked in reticulocyte maturation, red cell aging, and removal. The work of Higgins and Mahadevan[26] has identified a volume of clearance (V_c) below which red cells are cleared from the circulation: V_c is approximately 72 fL in normal cells and 59 to 56 fL for hypochromic cells like those of β-thalassemia trait and iron deficiency anemia. Clearance of red cells from circulation is preceded by a reduction in both Hb content and cell volume, which is associated with fluctuations or drift (D) around the average MCHC for individual cells. These variations in Hb content (D_h) and cell volume (D_v) can be extracted from the data collected with a regular CBC and reticulocyte count. D_h is markedly elevated in iron deficiency anemia and has a 98% diagnostic accuracy in distinguishing this condition from β-thalassemia trait (D_h threshold of 0.0045) in one 50-patient test cohort.

Almost all analyzers are capable of providing automated counting of reticulocytes.[27,28] Automated counting is more precise and accurate than manual counting.[29] Absolute reticulocyte counts are easily obtained with these instruments, thereby obviating the limitations of counting reticulocytes only as a percentage or correcting for changes in Hct (corrected reticulocyte count).

Some analyzers can perform direct measurements of reticulocyte Hb content. Reticulocyte indices like CHr have better diagnostics power than traditional biochemical parameters for diagnosing iron-deficient states and are an early indicator of therapeutic response to hematinic supplements like iron, B_{12}, or folate.[30] CHr[31,32] has been shown to be a valuable parameter in identifying iron deficient states in young children and toddlers.[33,34]

An additional useful feature of automated reticulocyte counters is that stress reticulocytes can easily be identified by their increased volume and RNA content.[35] Immature reticulocyte fraction (IRF) quantifies changes in reticulocyte maturity based on the increased fluorescence associated with the more immature reticulocyte forms. IRF has been show to be an early indicator of engraftment following hematopoietic stem cell transplantation.

The Blood Film

Automatic slide maker/stainer instruments are widely used in clinical laboratories; however, films made on coverslips are preferable to those made on glass slides because a greater proportion of blood on the coverslip film is technically suitable for microscopic examination. Proper processing of blood films on coverslips is fast becoming a lost art. The details of preparation and examination can be found in a variety of manuals of laboratory hematology, but the lucid and succinct instructions of Wintrobe deserve reproduction here[36]:

1. Use a small drop of blood, only 2 to 3 mm in diameter, taken either from a stylet wound, as described earlier, or from a syringe or needle tip used in venipuncture immediately after the venipuncture has been performed (anticoagulants are not to be used because they will alter the morphologic appearance).
2. Hold the coverslips only by their edges, placing one crosswise over the other, and allow the blood to spread between them for about 2 seconds.
3. Quickly but gently separate the coverslips by pulling them laterally, in opposite directions to one another but in the plane of the spreading film, just before the film reaches the edges (do not squeeze or lift the coverslips from one another).
4. Quickly air-dry the films, either by placing them face up on a clean surface if the humidity is low or by moving them through the air while holding them by their edges with your fingertips.

If the procedure has been carried out successfully, the blood will be spread evenly, and there will be no holes or thick areas in the preparation. A multicolored sheen will be seen on the surface of the dried, unstained film if light glances off it at the proper angle because the thin layer of closely fitting cells acts like a diffraction grating. Later under the microscope after staining, the red cells will be seen next to each other, but neither overlapping nor in rouleau formation, and central pallor will be visible; lymphocytes will have a readily distinguished cytoplasm rather than a minimal zone bearing closely on the nucleus, as occurs with thick films or those that dry too slowly.

Examination of a peripheral blood film is an essential step in the initial evaluation of a patient with anemia. The blood film should first be examined under low power to determine the adequacy of cell distribution and staining. Signs of poor blood film preparation include loss of central pallor in red blood cells, polygonal shapes, and artifactual spherocytes. Artifactual spherocytes, in contrast to true spherocytes, show no variation in central pallor and are larger than normal red cells. One should never attempt to interpret a poorly prepared blood film.

After the adequacy of the blood film is determined by low-power examination, the blood film should be examined first under 50× magnification and then under 1000× magnification. Low-power examination is crucial to identify the presence of rare cells like nucleated red cells.

Cells should be graded for size, staining intensity, variation in color, and abnormalities in shape. The blood film should also be examined for the presence of basophilic stippling and red cell inclusions. The significance of some of these findings is described in Table 9-3. Table 9-4 provides a comprehensive description of the morphologic abnormalities that can be observed in a blood film. Some representative smears of the most common hematologic disorders are presented in Figure 9-5.

Red cell hemolytic disorders can be classified according to their predominant morphology. An approach to such a classification is presented in Box 9-6, and it is discussed in detail in Chapters 14 through 17. Examination of the other cell lines may provide additional useful information: Neutrophil hypersegmentation (at least 5% of neutrophils with five lobes or at least 1% with six lobes) is suggestive of folic acid deficiency.

In addition to careful history and physical exam, examination of the blood smear by an experienced hematologist is an essential step in the proper diagnosis of all anemias.

TABLE 9-3 Diagnostic Significance of Red Cell Inclusions

Inclusion	Staining Agent	Diagnostic Significance
Basophilic stippling	Wright stain	Represents aggregated ribosomes; may be observed in thalassemia syndromes, iron deficiency, syndromes accompanied by ineffective erythropoiesis and pyrimidine 5′-nucleotidase deficiency; particularly prominent in unstable hemoglobinopathies and lead poisoning
Howell-Jolly bodies	Wright stain	Represent nuclear remnants; observed in asplenic and hyposplenic states, pernicious anemia, dyserythropoietic anemias, and severe iron deficiency anemia
Cabot's rings	Wright stain	Appear as basophilic rings, circular, or twisted figures-of-eight; considered to be nuclear remnants or artifacts; observed in lead poisoning, pernicious anemia, and hemolytic anemias
Heinz bodies	Brilliant cresyl blue, methyl violet	Represent denatured or aggregated hemoglobin; observed in patients with thalassemia syndromes or unstable hemoglobins, after oxidant stress in patients with enzyme deficiencies of the pentose phosphate pathway, and in patients with asplenia or chronic liver disease
Siderocytes	Prussian blue counterstained with safranin O	Represent nonhemoglobin iron within erythrocytes; seen in increased numbers in the peripheral circulation after splenectomy; observed in increased numbers in patients with chronic infection, aplastic anemias, or hemolytic anemias

TABLE 9-4 Common Red Blood Cell Morphologic Findings

RBC Morphology	Morphologic Definition	Clinical Associations
Acanthocyte (spur cell)	RBC has irregularly distributed, variably sized, pointy projections off its surface	Advanced liver disease, hyposplenism, some dyslipidemias, pyruvate kinase deficiency, McLeod phenotype
Anisochromia	Variation in the amount of central pallor among a population of RBCs	Iron deficiency, myelodysplasia, hypochromic anemia posttransfusion
Anisocytosis	Variation in size among a population of RBCs	Common nonspecific finding; seen in iron deficiency, moderate or severe thalassemia, megaloblastic anemia, partially treated anemia of several causes, posttransfusion
Basophilic stippling: coarse	RBC has variably sized (up to large), basophilic granular discolorations across its entire cytoplasm, on a Wright-stained film	Thalassemia, lead poisoning, myelodysplasia, pyrimidine 5′ nucleotidase deficiency, post chemotherapy
Basophilic stippling: fine	RBC has small, uniform, punctate basophilic dots across its entire cytoplasm, on a Wright-stained film	Reticulocytosis, normal finding
Bite cell/blister cell	RBC has a semi-circular indentation in its outer cytoplasmic border; there may be a "roof" to this indentation (blister cell) or no roof (bite cell)	Oxidative hemolysis
Dimorphism	Two distinct populations of RBC are present, for example, microcytic and normocytic, or hypochromic and normochromic	Myelodysplasia, posttransfusion, partially treated iron deficiency
Echinocyte (burr cell)	RBC has regularly distributed, equally sized, rounded projections off its surface	Artifact, renal failure, posttransfusion, phosphate deficiency, burns
Elliptocyte	RBC is oval shaped	Iron deficiency, megaloblastic anemia, hereditary elliptocytosis, post chemotherapy
Heinz body	RBC has a submembranous or epimembranous small round mass, which can only be seen by supravital or specialized Heinz body stains; this body is not visible on a routine Wright-stained film	Oxidative hemolysis, hyposplenism

TABLE 9-4 Common Red Blood Cell Morphologic Findings—cont'd

RBC Morphology	Morphologic Definition	Clinical Associations
Howell-Jolly body	Solitary round mass, relatively large (e.g., approximately 10%-20% of the diameter of the RBC), within the hemoglobinized portion of the RBC; appears dark blue or purple on a Wright-stained film	Hyposplenism, erythroblastosis, myelodysplasia, megaloblastic anemia, post chemotherapy
Hypochromia	The zone of central pallor is > $^1/_3$ the diameter of the RBC	Iron deficiency, thalassemia, anemia of chronic disease
Irregularly contracted cell	The RBC is small, dark, and lacks a zone of central pallor; its outer margin is not spherical: it may appear dented, compressed, or otherwise "contracted"	Nonspecific finding seen in a variety of conditions including G6PD deficiency, hemoglobinopathies, and normal neonates
Pappenheimer body	Usually multiple small dark blue or purple granular inclusions, all within the hemoglobinized portion of the RBC; these occupy only one portion or region of the RBC, unlike basophilic stippling, which is more global throughout the entire RBC	Iron overload, hyposplenism, myelodysplasia
Piscocytes/fish cells	Teardrop-like cells with tapered end that resembles a fish's tail	Thalassemia trait/thalassemias
Polychromasia	RBCs show color variability as a population: some (usually the majority) are the usual red color, while others are bluish	Reticulocytosis, normal neonate
RBC agglutination	Some RBCs aggregate into multicellular masses resembling a bunch of grapes	Cold agglutinin, cold autoimmune hemolytic anemia
Rouleaux	Some RBCs aggregate into linear patterns, said to resemble a stack of coins	Normal finding in the thick part of the blood smear, hypergammaglobulinemia (monoclonal or polyclonal)
Schistocyte	The RBC appears to have been fragmented: it lacks the usual circular shape, instead showing a triangular or other angulated morphology; the zone of central pallor is often missing	RBC fragmentation syndromes, for example, microangiopathic hemolytic anemia and hemolysis secondary to cardiac valve
Sickle cell	There are several sickle RBC morphologies, including the classic sickle (crescentic with two sharply pointed ends) or boats (linear with two tapered, if somewhat rounded, ends)	Severe sickling syndrome, for example, Homozygous Hb S disease, Hemoglobin SC disease, Hemoglobin SD disease
Spherocyte	The RBC is smaller and darker than normal; there is no zone of central pallor; the outer edge must be almost perfectly round (to differentiate this cell from irregularly contracted cells)	Autoimmune hemolytic anemia, alloimmune hemolytic anemia (e.g., hemolytic disease of the newborn), hereditary spherocytosis
Stomatocyte	The zone of central pallor is linear rather than circular; usually the line of pallor runs parallel to the long axis of the RBC; if the latter is ovoid, but in certain variants (e.g., South East Asian ovalocytosis), the line may run across the long axis or may be nonlinear, for example, bifurcated or trifurcated	Artifact, obstructive liver disease, hereditary stomatocytosis, South East Asian ovalocytosis, Rh null syndrome
Target cell	The RBC has a central red area within the zone of central pallor	Thalassemia, liver disease, hyposplenism, Hgb C disease or SC disease, hereditary xerocytosis; may be seen in iron deficiency
Teardrop cell	The RBC is tapered to a point at one end, resembling the classic artist's rendition of a drop of water	Nonspecific finding seen in several conditions, including myelofibrosis

Box 9-6 Classification of Red Cell Hemolytic Disorders by Predominant Morphology[*]

SPHEROCYTES

Hereditary spherocytosis
ABO incompatibility in neonates
Immunohemolytic anemias with IgG- or C3-coated red cells[†]
Acute oxidant injury (hexose monophosphate shunt defects during hemolytic crisis, oxidant drugs, and chemicals)
Hemolytic transfusion reactions[†]
Clostridium welchii septicemia
Severe burns, other red cell thermal injury
Spider, bee, and snake venom
Severe hypophosphatemia
Hypersplenism[‡]

BIZARRE POIKILOCYTES

Red cell fragmentation syndromes (microangiopathic and macroangiopathic hemolytic anemias)
Acute oxidant injury[‡]
Hereditary elliptocytosis in neonates
Hereditary pyropoikilocytosis

ELLIPTOCYTES

Hereditary elliptocytosis
Thalassemias
(Other hypochromic-microcytic anemias)
(Megaloblastic anemias)

STOMATOCYTES

Hereditary stomatocytosis
Rh_{null} blood group
Stomatocytosis with cold hemolysis
(Liver disease, especially acute alcoholism)
(Mediterranean stomatocytosis)

Box 9-6 **Classification of Red Cell Hemolytic Disorders by Predominant Morphology**—cont'd

IRREVERSIBLY SICKLED CELLS

Sickle cell anemia
Symptomatic sickle syndromes

INFRAERYTHROCYTIC PARASITES

Malaria
Babesiasis
Bartonellosis

SPICULATED OR CRENATED RED CELLS

Acute hepatic necrosis (spur cell anemia)
Uremia
Red cell fragmentation syndromes[‡]
Infantile pyknocytosis
Embden-Meyerhof pathway defects[‡]
Vitamin E deficiency[‡]
Abetalipoproteinemia
Heat stroke[‡]
McLeod blood group
(After splenectomy)
(Transiently after massive transfusion of stored blood)
(Anorexia nervosa)[‡]

TARGET CELLS

Hemoglobins S, C, D, and E
Hereditary xerocytosis
Thalassemias
(Other hypochromic-microcytic anemias)
(Obstructive liver disease)
(After splenectomy)
(Lecithin-cholesterol acyltransferase deficiency)

PROMINENT BASOPHILIC STIPPLING

Thalassemias
Unstable hemoglobins
Lead poisoning[‡]
Pyrimidine 5′-nucleotidase deficiency

NONSPECIFIC OR NORMAL MORPHOLOGY

Embden-Meyerhof pathway defects
Hexose monophosphate shunt defects
Unstable hemoglobins
Paroxysmal nocturnal hemoglobinuria
Dyserythropoietic anemias
Copper toxicity (Wilson's disease)
Cation permeability defects
Erythropoietic porphyria
Vitamin E deficiency
Hemolysis with infections[‡]
Rh hemolytic disease in neonates[†]
Paroxysmal cold hemoglobinuria[*‡]
Cold hemagglutinin disease[†]
Hypersplenism
Immunohemolytic anemia[†‡]

[*] Nonhemolytic disorders of similar morphology are enclosed in parentheses for reference.
[†] Usually associated with a positive Coombs test.
[‡] Disease sometimes associated with this morphology.

Thiamine-Responsive Megaloblastic Anemia
Hereditary Orotic Aciduria
3-Phosphoglyceride Dehydrogenase Deficiency

The metabolism of folate and that of cobalamin are intimately intertwined, and deficiency of either vitamin can manifest as megaloblastic anemia. The two deficiencies must be rigorously differentiated and treated specifically because their causes, mechanisms, nonhematologic expressions, courses, and prognoses differ. This is as true in pediatric medicine as in adult and geriatric medicine, from which much of the existing hematologic information originated. Recent advances in molecular biology, genetics, and epigenetics have increased our knowledge of cobalamin and folate metabolism. In addition, as biochemical tools to diagnose deficiencies have become more accurate and precise, the way that we define *deficiency* has expanded to include biochemically defined subclinical deficiency. Epidemiologic advances have connected disorders not traditionally linked to vitamin deficiency, such as neural tube defects (NTDs) and cardiovascular disease, suggesting potential means of preventing their development. Even if some of the epidemiologic information has still unsettled implications for clinical practice and public health, the wealth of new data deserves attention. In this chapter we review the relevant clinical and scientific knowledge from all these streams, emphasize its applications in pediatric hematology, and specify wherever possible the known distinctions between infants, older children, and adults.

DEFINITIONS

Megaloblastic anemia is a specific, relatively small subset of *macrocytic anemia*. It is defined by a characteristic megaloblastic appearance of nucleated cells that suggests maturational nuclear-cytoplasmic asynchrony. Despite the name "anemia," all three hematopoietic cell lines are affected noticeably as the deficiency advances. Pancytopenia can ultimately become extreme. The term *pernicious anemia,* sometimes misapplied to the megaloblastic anemia in cobalamin deficiency, is used here in its preferred, specific meaning: the absence of gastric intrinsic factor (IF) that produces cobalamin malabsorption and, ultimately, deficiency.

Deficiency is an elusive term with surprisingly limited conceptual and pragmatic consensus on its definition(s). Where relevant, in this chapter we will use *clinical deficiency* of cobalamin or folate to denote the presence of vitamin-specific clinical signs and symptoms that require medical intervention. However, most cobalamin and folate deficiencies identified today are *subclinical*. They are clinically silent and expressed only by (often minimal) biochemical manifestations; most importantly, the likelihood for progression is usually uncertain, and consensus does not yet exist for medical intervention or for according them the same weight as clinical deficiency.

The term *cobalamin* refers to all corrins with coenzyme activity in humans. *Vitamin* B_{12} originated as the name for synthetic *cyanocobalamin* but is widely used as a generic synonym for cobalamin. The term *folate* refers to synthetic folic acid and to the various natural folate coenzymes, which are reduced dihydrofolates and tetrahydrofolates and their single-carbon substituted forms. Most folates in nature are reduced and substituted *folate polyglutamates*.

The term *newborn* is used in this chapter for a child in the first month of life and the term *infant* for a child in the first 2 years of life.

HISTORY

The story of megaloblastic anemia began with Addison's description in 1849 of a puzzling disease that he believed had an adrenal origin[1,2] and whose lethality Biermer immortalized by calling it "pernicious anemia." A series of clinical and pathologic descriptions from the 1870s through the 1920s identified the hematologic and neurologic features of the disease, setting the stage for one of the landmark clinical investigations in hematology. Using reticulocyte counts as evidence, Minot and Murphy reversed the anemia by feeding patients large amounts of liver in 1926,[3] and for their findings they were awarded a Nobel Prize. Castle then proved with elegant clinical experiments that the disease was caused by the loss of an "intrinsic factor" in gastric juice that allowed the internalization of an extrinsic factor.[4] In the 1940s, the "extrinsic factor" was crystallized, identified, and synthesized as cyanocobalamin (vitamin B_{12}), which could then be injected intramuscularly. Readers are referred to very readable accounts of the compelling history of pernicious anemia.[5-7]

Another important story was developing on a separate track, in which somewhat similar clinical syndromes involving megaloblastic anemia ("pernicious anemia of pregnancy" and "tropical anemia") were described and shown by Wills to respond to yeast extract.[8] Folic acid was synthesized in 1948 and shown to reverse folate deficiency. A notable self-experiment in a single subject proved that folate deficiency induced by dietary restriction produced megaloblastic anemia and mapped the evolution of the hematologic changes prospectively.[9] After the synthesis of the two vitamins, work by many investigators solidified accurate biochemical testing for cobalamin and folate status and delineated the clinical differences between folate and cobalamin deficiencies. New tests with improved sensitivity and accuracy have been developed, although a gold standard for the diagnosis of deficiency remains elusive, especially for cobalamin deficiency.

Equally important have been the continuing advances over decades in delineating the complex transport system of each vitamin and the modern molecular and genetic understanding of the proteins and receptors involved. These advances are especially encouraging and important to pediatric care of cobalamin deficiency, which is not as common and had not heretofore been studied as intensively as in adults. The major advances in the past two decades and the explosion in diagnostic, biochemical, genetic, and therapeutic advances in identifying and treating new genetic disorders and the pathways they illuminate are reviewed within this chapter.

FOLATE

Chemistry of Folates

Folates are heterocyclic compounds consisting of a pteroyl group conjugated with one or more glutamic acid units (Fig. 10-1). Folic acid, or pteroylglutamic acid, is an oxidized folate consisting of pteroic acid conjugated with a single glutamate residue. Biologically active folates are derived from folic acid by reduction of its pterin ring to form 7,8-dihydrofolate (DHF) and 5,6,7,8-tetrahydrofolate (THF); by addition of single carbon units at different redox states to nitrogen 5 or 10 of the pterin ring; and by conjugation of up to seven total glutamate residues by γ-carboxyl bonding. Intracellular folates exist primarily as one-carbon group substituted tetrahydrofolate polyglutamates.

Folate derivatives that play an important role in cellular metabolism include 5-methylTHF, 5,10-methyleneTHF, 5,10-methenylTHF, 10-formylTHF, 5-formylTHF, and 5-formiminoTHF. Folic acid itself is available commercially as a stable yellow powder. It has low solubility in aqueous solutions and at acid pH. 5-FormylTHF (folinic acid, leucovorin) is a stable reduced folate that is available commercially. Other reduced folates are photolabile and susceptible to destruction by oxidation, readily

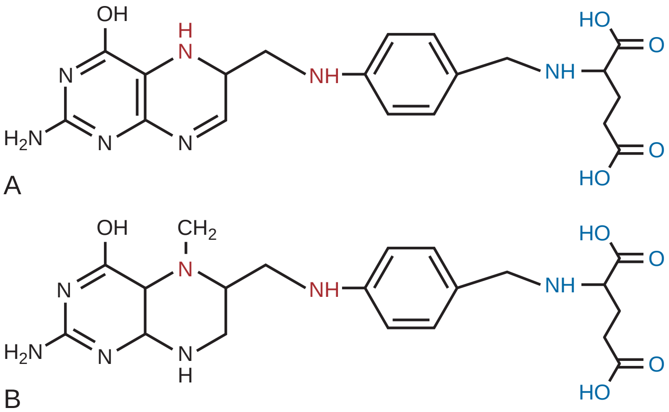

Figure 10-1 Structure of folic acid (A) and 5-methyltetrahydrofolic acid (B). Folic acid consists of pteroic acid *(black)* conjugated to a glutamic acid *(blue)*. Cellular folates are derived from this molecule by reduction to 7,8-dihydrofolate (DHF), further reduction to 5,6,7,8-tetrahydrofolate (THF); by addition of one carbon groups to THF at nitrogens 5 or 10 *(shown in red)*, and by addition of up to six additional glutamic acid residues γ-carboxyl bonding. Forms active in cellular metabolism include 5-methylTHF *(shown)*, 5-formiminoTHF, 5-formylTHF (folinic acid), 5,10-methyleneTHF, 5,10-methenylTHF, and 10-formylTHF.

breaking at the carbon 9—nitrogen 10 bond to produce inactive catabolites.[10]

Folate Polyglutamates

Most intracellular folates exist as polyglutamylated derivatives, containing up to six or seven glutamate residues attached by γ-peptide bonds.[11] Synthesis of these folate polyglutamates depends on activity of the enzyme folylpoly-γ-glutamate synthetase (EC 6.3.2.17), which adds glutamate residues one at a time to reduced folates, using adenosine triphosphate (ATP) as an energy source.[12] Folate polyglutamates have higher affinity for most folate-dependent enzymes than the corresponding monoglutamates and are efficiently channeled between active sites in multifunctional enzymes.[13] They do not readily cross the cell or mitochondrial membranes, and polyglutamylation of folates within cells thus contributes to the ability of cells to retain reduced folates in the presence of low extracellular concentrations. Separation of cytosolic and mitochondrial folate polyglutamate pools has important consequences for cellular folate metabolism.

Folate Sources, Requirements, and Stores

Folate is synthesized de novo by bacteria, plants, fungi, and certain protists. Animals are dependent on their diets for adequate supplies of the vitamin. Foods with very high folate content include dark green vegetables, orange juice, nuts, legumes, and liver. However, the reduced folates present in food are labile to light and oxidation and are partly destroyed during processing and cooking. The recommended daily allowance for folate is expressed in dietary folate equivalents to take into account the greater bioavailability of folic acid than the reduced polyglutamylated forms present naturally in food. Values recommended by the Institute of Medicine of the United States[14] and the World Health Organization[15] are listed in Table 10-1.

The average content of body stores in adults has been estimated to be 12 to 28 mg folate, based on a content of 6 to 14 mg (or 4.5 to 10 μg/g) in liver, the major storage organ.[14,16] It is relevant to note here that the ratio of body folate stores to recommended daily intakes is less than 100 : 1, whereas the ratio for cobalamin approximates 1000 : 1. As a result, the folate depletion necessary to produce megaloblastic anemia is achieved much more rapidly than depletion of cobalamin. Storage data are sparse in children, but infants of normal birth weight who died in the perinatal period had hepatic folate contents of 0.76 mg[16]; low-birth-weight infants' hepatic content averaged only 0.13 mg. These data, although not fully representative, suggest much lower stores–to–recommended intake ratios in newborns and infants than in adults.

Recognition that supplementation in the periconceptional period with folic acid results in decreased occurrence and recurrence of NTDs in children of women with no clinical evidence of folate deficiency[17,18] led to recommendations that all women of childbearing years should take folate supplements (200 to 400 μg daily), because the critical period for prevention of NTDs is early in pregnancy before most women are aware that they are pregnant. Since January 1998, folic acid fortification of all enriched cereal-grain products has been mandated in the United States,[19] Canada, and parts of South America. As a result, serum and red blood cell (RBC) folate concentrations have increased in these populations and the incidence of NTD-affected pregnancies has decreased by 26% in the United States and by 48% in Canada.[20,21] Concerns about folate fortification delaying the diagnosis of cobalamin deficiency, promotion of cancer growth, and issues of free choice have delayed mandating folate addition to the diet in Europe and elsewhere.[22]

TABLE 10-1 Recommended Daily Intakes for Folate

Age/Condition	Institute of Medicine (1998) μg/day (DFE)	World Health Organization (2004) μg/day (DFE)
0-6 mo	65*	80
7-12 mo	80*	80
1-3 yr	150	160
4-8 yr	200	4-6 yr: 200 7-9 yr: 300
9-13 yr	300	300
>14 yr	400	400
Pregnancy	600	600
Lactation	500	500

DFE, Dietary folate equivalent.

*Values are expressed as "adequate intake" rather than recommended daily allowance.

The median serum folate level of 5.5 μg/L in the total National Health and Nutrition Examination Survey (NHANES) study population before fortification increased to 11.9 μg after fortification[23]; in children, folate level increased from 8.8 to 15.6 μg/L for ages 4 to 11 years and from 5.1 to 11.0 μg/L for ages 12 to 19 years. The mildly lower folate status in adolescents, albeit still within the reference range,[14] is unexplained. The median RBC folate level increased from 174 to 256 μg/L in the total population,[23] and in children it increased from 200 to 256 μg/L at ages 4 to 11 years and from 150 to 224 μg/L at 12 to 19 years. NHANES data after fortification estimated that daily folate intake averaged 626 μg in men and 534 μg in women.[24] Intakes in children averaged 425 μg at ages 1 to 3 years, 642 μg at 4 to 8 years, 600 μg at 9 to 13 years, and 606 μg at 14 to 18 years[24]; the total homocysteine (tHcy) levels in the age groups between 4 and 18 years old were within the expected reference range (4.6 to 5.2 μmol/L).

Physiology of Folates

Cellular Folate Uptake

Three distinct systems for cellular uptake of folates have been identified in mammals. The reduced folate carrier (RFC) supports a low-affinity, high-capacity system for uptake of reduced folates and methotrexate (an antifolate drug) at high concentrations (in the micromolar range) with a neutral optimum pH; it is less effective in uptake of folic acid. It appears to be an important folate transporter in many types of cells, including hematopoietic cells. RFC is encoded by the *SLC19A1* gene on chromosome 21q22.3.[25-27] Inactivation of *Slc19a1* in mice results in neonatal lethality owing to failure of erythropoiesis.[28]

A second, high-affinity low-capacity system for folate uptake, active at nanomolar folate concentrations, is mediated by members of the folate receptor family. Several different receptors have been identified, encoded by genes on the long arm of chromosome 11 (*FOLR1, FOLR2, FOLR3,* and *FOLR4*), with different forms expressed at different times in different tissues.[29-31] Folate receptor-α and folate receptor-β are attached to the cell surface by a glycosylphosphatidylinositol anchor.[32] The circulating folate-binding protein that carries some of the circulating folate is derived from folate receptor-α by cleavage from this anchor. Binding of folates to folate receptors initiates carrier-mediated endocytosis. The level of cell surface folate receptors increases greatly in cultured mouse cells grown in very low folate concentrations, suggesting that these receptors play an important role in cellular folate uptake under these conditions.[33]

The third folate transport protein, the proton-coupled folate transporter (PCFT), has an acidic optimal pH, and transports reduced and oxidized folates with similar efficiency.[34] It is expressed at high levels in liver, kidney, and small intestine, with lower expression in other tissues. It was originally identified as a low-affinity heme transport protein[35] but was subsequently shown to have higher affinity for folates. PCFT is encoded by the *SLC46A1* gene on chromosome 17q11.2.[34]

Absorption of Folates from the Gut

Dietary folates are principally folate polyglutamates. These are hydrolyzed within the gut lumen or brush border, or in the lysosomes of enterocytes, by the enzyme γ-glutamylhydrolase (EC 3.4.22.12),[36,37] to generate folate monoglutamates that cross cell membranes much more easily than the corresponding polyglutamates. Adequate absorption is impossible without this hydrolysis. Uptake of folate monoglutamates occurs primarily in the proximal small intestine and is mediated by PCFT.[34] RFC is also expressed in enterocytes, but its role in this tissue remains unknown. The efficiency of absorption of folic acid, folate polyglutamates, and food folate varies in different subjects. In general, absorption of synthetic folic acid is about twice as efficient as that of folate in food whereas folic acid from folic acid–fortified cereal grain food is absorbed about 1.7 times as efficiently as food folate.[38] The carrier-mediated process in the proximal small intestine for reduced folates is saturable, with an upper limit approximating 200 μg of food folate. The absorption of unreduced folic acid, when taken in large doses, occurs more distally by nonsaturable high-capacity mechanisms,[4,39] which helps explain both the higher bioavailability of folic acid than food folates and the frequent response to oral folic acid by patients with malabsorptive disease.

Folate appears in the portal venous blood within 15 minutes of entering the stomach and reaches a maximum level in portal venous plasma about 1 hour later. Reduced folates, such as 5-formylTHF, are rapidly converted to 5-methylTHF during absorption.[40] A second potential source of folate is that synthesized by bacteria in the colon, some of which exists as monoglutamates. There is evidence for a folate transport system, with the same properties as the small intestine system, in the colon.[41,42] This may contribute to whole-body folate homeostasis, or at least support folate requirements of colon cells.

It has been estimated that up to 100 μg of folates, including folate delivered to the liver and some hepatic folate, is excreted into the bile and subsequently reabsorbed.[43-45] This enterohepatic recirculation mediates a slower and more even absorption than would occur in its absence. There is evidence that enterohepatic recirculation of folates is impaired with alcohol ingestion,[44,46] contributing to folate deficiency.[47,48]

Transport of Folates in Plasma

Plasma folate typically consists almost entirely of 5-methylTHF, but significant amounts of folic acid may be present in individuals who have consumed folic acid supplements or food supplemented with folic acid.[49-51] Most folate circulates unbound, although some may be bound to albumin and a small proportion is bound to a folate-binding protein derived from the cell surface protein folate receptor-α.[52-54] Plasma folate-binding protein levels are increased in pregnancy, in folate deficiency, in renal failure, with breast and ovarian cancers, and with some types of inflammation. Its function in plasma is unclear.[55-57] It is present in milk, where it may function to improve the absorption of folate by the newborn.[58,59]

Folate Transport Across the Blood-Brain Barrier

The concentration of folate (primarily 5-methylTHF) in the cerebrospinal fluid (CSF) is twofold to threefold higher than in blood, indicating active transport occurs across the blood-brain barrier.[60] Both PCFT and folate receptor-α are expressed at the choroid plexus, and mutations at either *SLC46A1* or *FOLR1* are associated with decreased cerebral 5-methylTHF levels. It has been suggested that folate receptor-α mediates endocytosis of folates and that PCFT is required for export of endocytosed folates from acidified endosomes.[61]

Folate in the Kidney

Folate, free and bound to folate-binding protein or albumin, is filtered at the glomerulus and reabsorbed in the proximal tubule, with the result that little folate appears in the urine. Both folate receptor-α and folate receptor-β are expressed in the brush border of the proximal tubule and are responsible for reabsorption of free folate.[62,63] Reabsorption of folate bound to albumin is carried out by the large multiligand endocytic receptors megalin and cubilin, whereas folate-binding protein is reabsorbed by megalin.[64]

Folate Transport in the Placenta

Levels of plasma folate are higher in cord than maternal blood.[65] Perfusion of the human placental cotyledon revealed a two-step maternal-to-fetal transfer of methylTHF, with binding of folate to placental folate-binding proteins on the maternally facing chorionic surface and gradual release generating an intervillous blood folate level three times that in the maternal circulation, followed by passive transfer to the fetal circulation along a downhill concentration gradient.[65] There is expression of folate receptor-α, PCFT, and RFC in placenta, with folate receptor-α and PCFT localizing together to the syncytiotrophoblast microvillous plasma membrane, where they may function together in the same way that they do in the choroid plexus.[66-69]

Biochemistry of Folates

Intracellular folate metabolism involves the transfer of one-carbon units derived from breakdown of a variety of metabolites. A scheme of cellular folate metabolism is illustrated in Figure 10-2. Metabolism can be divided into reactions involved in transfer of one-carbon units to THF, generating one-carbon substituted reduced folates; interconversion of one-carbon substituted THF derivatives; and utilization of one-carbon units in amino acid and nucleic acid metabolism.

The primary source of one-carbon units for folate metabolism is catabolism of serine to form glycine, which generates 5,10-methyleneTHF (reaction 4 in Fig. 10-2). Additional sources include breakdown of glycine (reaction 5), dimethylglycine and sarcosine, which also

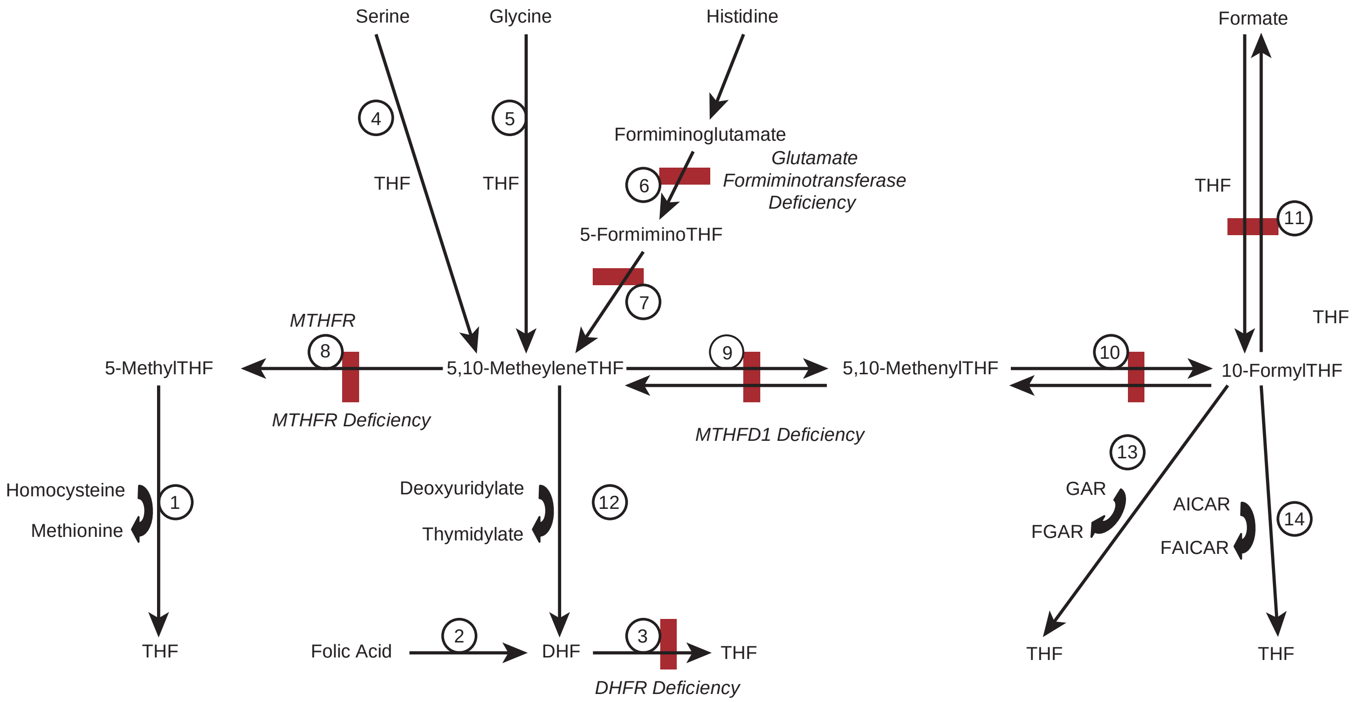

Figure 10-2 Cellular folate metabolism. Sources of one-carbon units are shown in the upper part of the figure, and reactions that consume one-carbon units are shown in the lower part. Steps blocked in the four confirmed disorders of folate metabolism are shown by *red bars;* note that glutamate formiminotransferase deficiency affects both glutamate formiminotransferase (reaction 6) and formiminotetrahydrofolate cyclodeaminase (reaction 7) activities, which are carried on a single protein; and MTHFD1 deficiency affects methyleneTHF dehydrogenase (reaction 9), methenylTHF cyclohydrolase (reaction 10), and formylTHF synthetase (reaction 11). Reactions are numbered as in the text. *1,* Methionine synthase; *2* and *3,* dihydrofolate reductase; *4,* serine hydroxymethyltransferase; *5,* the glycine cleavage system; *6,* glutamate formiminotransferase; *7,* formiminoTHF cyclodeaminase; *8,* methyleneTHF reductase; *9,* methyleneTHF dehydrogenase; *10,* methenylTHF cyclohydrolase; *11,* formylTHF synthetase; *12,* thymidylate synthase; *13,* GAR transformylase; *14,* AICAR transformylase.

generate 5,10-methyleneTHF, and breakdown of histidine, which generates 5,10-methenylTHF (reactions 6 and 7). ATP-dependent condensation of formate with THF to form 10-formylTHF is catalyzed by methylTHF synthetase (reaction 11). Once one-carbon units have been attached, the various forms can be interconverted to ensure that the cell has the folate derivatives required for metabolism. 5,10-MethyleneTHF can be reduced to form 5-methylTHF by the enzyme methylenetetrahydrofolate reductase (MTHFR; reaction 8). Alternatively, it can be oxidized to form 5,10-methyleneTHF and 10-formylTHF by the multifunctional enzymes encoded by *MTHFD1* in the cytoplasm or *MTHFD2/MTHFD2L* in mitochondria (reactions 9 and 10).

One-carbon substituted forms of cobalamin are required for several critical steps in metabolism.

1. Methylation of homocysteine to form methionine is catalyzed by methionine synthase and utilizes 5-methylTHF as methyl group donor (see Fig. 10-2, reaction 1); this reaction also requires cobalamin and S-adenomethionine to function and represents the point in cellular metabolism where folate and cobalamin metabolism interact. Methionine is not only required for protein synthesis; it can also be converted to S-adenosylmethionine, which is the methyl group donor in a large number of transmethylation reactions that are involved in DNA and RNA methylation and in neurotransmitter synthesis, among other processes.
2. Conversion of deoxyuridylate to deoxythymidylate, the final step in thymidine synthesis, utilizes 5,10-methyleneTHF as its one-carbon unit donor (see Fig. 10-2, reaction 12). This reaction generates DHF, which must be reduced to THF before it can be used again as a one-carbon unit recipient. This reduction is accomplished by DHF reductase (see Fig. 10-2, reaction 3).
3. Two separate steps in de novo purine biosynthesis use 10-formylTHF as a one-carbon donor, generating carbons 2 and 8 of the purine ring structure (see Fig. 10-2, reactions 13 and 14).

Folates and Arteriosclerotic Vascular Disease

Homocysteine was first implicated as an atherogenic factor by the observation of premature arteriosclerotic disease in children with severe hyperhomocysteinemia due to inborn errors of metabolism.[37] It was subsequently suggested that moderate elevations of tHcy were associated with development of atherosclerotic disease in adults. A common thermolabile variant of MTHFR, c.677C→T (p.A222V), results in an approximately 50% decrease in enzyme activity when present in the homozygous state[70] and in elevated tHcy in the presence of low folate concentration.[71] Many observational studies showed an association between elevated tHcy and cardiovascular disease and a modest, but statistically significant, increased risk for cardiovascular disease in patients with the T allele.[72] However, suggestions that lowering tHcy might improve cardiovascular outcomes in patients have not been supported in several large epidemiologic studies.[73-75]

Folates and Neural Tube Defects and Other Birth Defects

As noted previously, folate supplementation during the periconceptional period (from initiation of pregnancy to closure of the neural tube at about 1 month of gestation) reduces the occurrence and recurrence[17,18] of NTDs, leading to fortification of flour and other enriched grain products with folic acid in the United States and other countries. This has been associated with a decrease in prevalence of NTDs.[76-80] Studies have also suggested a role for folate supplementation in preventing nonsyndromic cleft lip with or without cleft palate[81-83] and congenital heart defects,[84,85] but the evidence for these associations is not as strong.[86-88]

Folates and Cancer

Folate status appears to have an inverse relationship with the risk for cancers of various types. However, epidemiologic studies have also suggested an association between higher folate status and progression of premalignant lesions in several tissues,[89-91] and increased folate concentrations have been associated with growth of some malignant cells.[92] The effects of folate have been most thoroughly investigated in colorectal cancer, where results of meta-analysis were consistent with a small protective effect of folate against risk for cancer.[93] There is less convincing evidence for a protective role for folate against cancers of the oropharynx, esophagus, stomach, pancreas, lungs, cervix, ovary, and breast as well as for neuroblastoma and leukemia.[92] A transient increase in the rate of colorectal cancer in the United States and Canada following the start of folic acid fortification of grains may reflect the effect of increased folate concentration on proliferation of existing adenomas, however.[94] Meta-analyses of studies of folic acid supplementation (at levels tenfold higher than those used in folic acid fortification of grain) showed no effect on the rate of cancer.[73,95]

Folate Antimetabolites

Antifolates are analogues of folic acid that block folate metabolism, interrupting DNA synthesis and causing cell death. Methotrexate, a potent inhibitor of mammalian DHF reductase, is effective in combination chemotherapy of carcinomas of the breast, lung, bone, ovary, head and neck, and elsewhere and contributes to cure of choriocarcinoma and childhood acute lymphoblastic leukemia. It is also used for its immunosuppressive and antiproliferative properties in the treatment of psoriasis, rheumatoid arthritis, and graft-versus-host disease after bone marrow transplantation. Newer antifolates have been synthesized and tested over the past 40 years. Some are discussed in Chapter 46, "Chemotherapy in the Pediatric Cancer Patient."

Pyrimethamine is an antimalarial drug with greater affinity for parasitic than human DHF reductase. Trimethoprim is an antifolate with antibacterial activity and a higher affinity for bacterial than human DHF reductase. In combination with sulfisoxazole, which interferes with bacterial synthesis of folic acid, there is a double synergistic antifolate attack on bacteria. Such combinations are often used to treat urinary tract and other infections and as prophylaxis against pneumonia resulting from

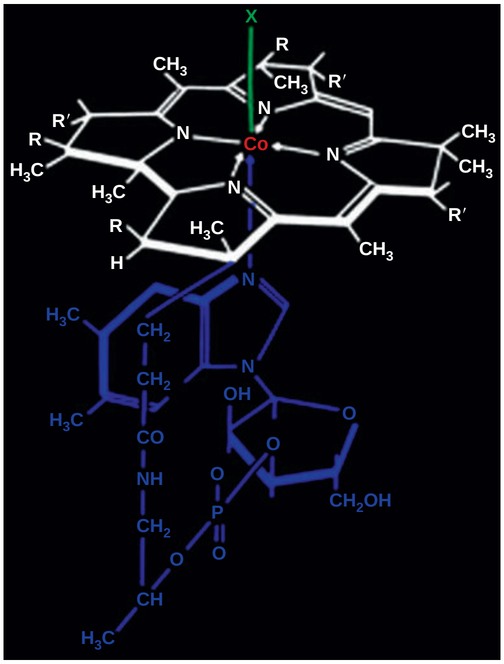

Figure 10-3 Structure of cobalamin. Cobalamin (vitamin B_{12}, Cbl) consists of a planar corrin ring *(black)* that coordinates with a central cobalt atom *(red)*, with a 5,6-dimethylbenzimidazole base *(blue)* covalently attached to the corrin ring and coordinating with the cobalt atom. X *(green)* represents the upper axial ligand, which varies in different biologic and pharmacologic cobalamins. When X is methyl, the compound is methylcobalamin (MeCbl); when it is adenosyl, the compound is 5-deoxyadenosylcobalamin (AdoCbl); when it is CN, the compound is cyanocobalamin (CNCbl); and when it is OH, the compound is hydroxocobalamin (OHCbl).

infection with *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) in immunocompromised patients.

COBALAMIN (VITAMIN B_{12})

Chemistry of Cobalamins

Cobalamins, members of the class of molecules called corrins, have the chemical structure shown in Figure 10-3. They consist of a planar corrin ring, similar to but distinct from that of porphyrins such as heme, with a central cobalt atom that coordinates with four nitrogen atoms of the corrin ring. A nucleotide, 5,6-dimethylbenzimidazole, coordinates with the cobalt atom below the plane of the corrin ring and attaches covalently as well to the corrin ring. The central cobalt atom may exist in three different oxidation states: the oxidized trivalent state (cob[III]alamin), the divalent state (cob[II]alamin), and the fully reduced monovalent state (cob[I]alamin). Several different groups may be coordinated to the cobalt atom in the upper axial position (position "X" in Fig. 10-3) when it is in the cob(III)alamin state. Corrins that have coenzyme activity or can be converted to coenzyme forms within the cell include cobalamins with cyanide (cyanocobalamin [CNCbl]), the hydroxyl radical (hydroxocobalamin [OHCbl]), the methyl radical (methylcobalamin [MeCbl]), or 5′-deoxyadenosyl (adenosylcobalamin [AdoCbl]) bound in the upper axial position, as well as cob(II)alamin and cob(I)alamin.[96,97] Under certain conditions, for example at acidic pH or when bound to certain proteins, cobalamin can exist in a "base off" conformation, in which the dimethylbenzimidazole base no longer coordinates with the central cobalt atom.

Cobalamin Sources, Requirements, and Stores

Nutritional Sources and Requirements

Although prokaryotes, animals, and many algae require cobalamin for metabolism, only prokaryotes synthesize it.[98] Humans depend on microbial cobalamin, usually obtained second-hand through consumed animal-derived products, for their cobalamin requirement.[16,99,100] Multicellular plants or fungi do not synthesize or accumulate cobalamin and thus do not contribute it to the diet. Many prokaryotes synthesize and utilize corrinoids other than cobalamin, containing a lower axial ligand other than dimethylbenzimidazole or lacking a lower ligand entirely that cannot be utilized by humans.[101] The human cobalamin transport system largely excludes these analogues from internalization by cells.

The estimated daily cobalamin loss is 1 μg in adults,[99] with wide individual variations. Much of the loss is biliary.[102] Estimates of daily intake requirement have varied, in part because of different end points for sufficiency. The Institute of Medicine[99] reviewed available dietary data to set requirements for children of all ages, adults, and pregnant and lactating women (Table 10-2). The recommended daily intake of cobalamin for adults is set at 2.4 μg/day, on the assumption that the expected 50% absorption rate of such an amount from food will replace the estimated daily losses while leaving a cushion for individual variability. A subsequent Scandinavian study of adults found that metabolic status leveled off with ascending daily intakes that approximated 4.2 μg or even 6 to 7 μg,[103,104,105] but interpretations should be

TABLE 10-2 Recommended Intakes of Cobalamin Throughout Life

	Age Group	Recommended Daily Intake* (μg Cobalamin)
Infancy	0-6 mo 7-12 mo	0.4 0.5
Childhood	1-3 yr 4-8 yr 9-13 yr 14-18 yr	0.9 1.2 1.8 2.4
Adulthood	19-50 yr	2.4
Pregnancy		2.6
Lactation		2.8

Data from the recommendations of the Institute of Medicine review and analysis of dietary reference intakes.[99]

*The amounts reflect recommended dietary allowances, which are derived from estimated average requirements by adding twice the latter's coefficient of variation in order to include individuals whose requirements may lie at the extremes. For infants, however, the shown values represent adequate intake, based on evaluation of published data on breastmilk intakes that appeared to provide normal cobalamin status.

tempered by the limitations of the short-term dietary assessments for cobalamin, the biomarker end points, and the study populations (e.g., a striking overrepresentation of vegetarians in one study).

Analysis of NHANES data from 2003 through 2006 showed that median daily cobalamin intake was 6.4 µg (95% confidence interval [CI], 4.7 to 8.6 µg) in males and 5.0 µg (95% CI, 3.7 to 6.9 µg) in females.[24] It is useful to note that the daily intakes reported by NHANES[24] exceeded the Institute of Medicine's recommendations in children (see Table 10-2). The intakes were 5.1 µg at ages 1 to 3 years, 6.1 µg at 4 to 8 years, 5.6 µg at 9 to 13 years, and 5.9 µg at 13 to 19 years. The 95% confidence intervals for these intakes exceeded the Institute's estimated requirements, and the children's 95% confidence levels for methylmalonic acid (MMA) levels were within the expected reference ranges.[24] Data were unavailable for infants.

Foods vary widely in cobalamin content.[100] Liver and some seafood are among the richest in cobalamin but are not eaten often, beef has relatively rich cobalamin content, and cobalamin content of eggs and milk is smaller. However, bioavailability can vary as much as tenfold among different food sources,[100] and food cobalamin content, whose measurement can be imprecise, does not always predict effectiveness. Thus cow's milk and fortified cereal, as well as fish, proved to be much more efficient providers of cobalamin than meat, despite the latter's high cobalamin content.[100,104,106] The specific receptor-mediated absorption of cobalamin via IF allows efficient absorption of more than 50% of this micronutrient while also excluding unutilizable corrinoid analogues. However, this mechanism is also easily saturable, and when more than 1 to 2 µg is ingested in a meal, much of the excess is relegated to nonspecific diffusion in which absorptive bioavailability falls to approximately 1%.[16,107] The implications of such a small margin between the desirable level of intake and the total capacity of receptor-specific absorption have not been explored sufficiently. However, the existence of haptocorrin, a ubiquitous, relatively abundant, high-affinity cobalamin-binding protein that does not mediate specific delivery to intestinal cells or other tissue, raises the obvious question whether such an upper limit on cobalamin internalization serves a positive but still undefined biologic purpose, perhaps tied to corrin analogue exclusion from cells.

Cobalamin Requirement in Infancy. Most of the information on cobalamin physiology and economy has been obtained in adults, which may apply to older children and adolescents also. However, data are limited in newborns and infants, who may differ considerably. Current estimates of the cobalamin requirement for infants are based on the 0.3 to 0.4 µg of cobalamin provided daily in breastmilk from mothers with apparently normal cobalamin status.[16,99] However, recent data suggest that breastmilk may be a poor model.[108] Cow's milk contains not only much more cobalamin[16,109] but its cobalamin is also carried by transcobalamin and may therefore be more bioavailable than the haptocorrin-bound cobalamin of human breastmilk.[109]

Cobalamin Stores

Estimates of stores vary with assessment methods and subject selection. The current consensus is that cobalamin contents in adults average 2 to 3 mg, with wide spreads.[99] The liver contains approximately 1.5 mg of those stores, with concentration ranges of 0.7 to 1.5 µg/g.[16] By comparison, liver concentration is 0.02 to 0.14 µg/g in patients with megaloblastic anemia caused by pernicious anemia, which is a reduction of more than 80%. Store estimates are scarce in children. Maternal-fetal cobalamin transfer favors the fetus even when maternal stores are limited, and cord blood cobalamin levels exceed maternal serum levels, 370 versus 240 ng/L,[99] although maternal serum cobalamin levels tend to be spuriously low during pregnancy. Full-term newborns have a mean liver cobalamin content of 27.3 µg[110]; the total liver content is only 10.7 µg in premature newborns and 4.1 µg in the fetus. The total body cobalamin store in newborns is approximately 50 µg, which illustrates how greatly stores need to expand between infancy and adulthood. As will be discussed, the approximately 1000 : 1 stores-to-daily intake ratio in adults and adolescents may be only 100 : 1 in newborns.

Physiology of Cobalamin

Cobalamin-Binding Proteins

Cobalamin does not exist free in the body outside the gastrointestinal tract, where its carrier-free existence is transient. Cobalamin traffic, transport, and access to cells depend on three cobalamin-binding proteins: IF, transcobalamin, and haptocorrin. Only IF and transcobalamin interact with specific cell receptors, allowing efficient cellular internalization of cobalamin at low concentrations, but these systems have relatively low capacity.[107] These binding proteins have similar primary sequences, and their genes have similar intron/exon structure, suggesting that they arose by duplications of an ancestral gene.[111,112] They show 33% overall homology with each other, and specific regions demonstrate as much as 60% to 80% identity.[113]

IF is a 45-kD glycoprotein synthesized by gastric parietal cells in humans; under some circumstances, ectopic IF synthesis may also occur in chief cells, which are the normal synthetic site in many other mammals.[114] IF mediates efficient uptake of cobalamin in the intestine. It binds cobalamins less tightly than does transcobalamin or haptocorrin[115] but has far greater binding affinity for cobalamins than for nonfunctional corrin analogues, which helps limit the analogues' intestinal absorption. IF is encoded by the *GIF* gene on chromosome 11q13.[116]

Transcobalamin (also called transcobalamin II) is synthesized by endothelial and other cells, and mediates entry of cobalamin into most types of peripheral cells.[117] It is a nonglycosylated protein with a molecular weight of 43 kD[118] that, like IF, binds cobalamin tightly but has low affinity for cobalamin analogues. Transcobalamin content is small in many secretions.[117] The *TCN2* gene is on chromosome 22q12-13.[112]

Haptocorrin (also called transcobalamin I) differs from IF and transcobalamin in having a high affinity for nonfunctional corrinoid analogues as well as for cobalamin and in having no specific cellular receptors for its internalization. These characteristics suggest an important role in excluding analogues, and perhaps excess cobalamin, from cells. The protein, encoded by the *TCN1* gene on chromosome 11q12.1,[119] is approximately 46 kD, but its heavy glycosylation creates glycoproteins of different sizes, isoelectric points, and plasma clearance rates. The glycosylation variability, which is sometimes secretion specific, led to artificial distinctions and names for haptocorrin variants (e.g., transcobalamin III and R binder), which are no longer used. Haptocorrin is synthesized in myeloid precursors at early stages when specific granules form[120]; this appears to be the chief source of plasma haptocorrin. Epithelial or ductal cells of exocrine glands also synthesize haptocorrin and are its source in secretions, where haptocorrin achieves concentrations much higher than in plasma.[117,121,122] The secretions include bile, saliva, tears, breastmilk, bronchial secretions, amniotic fluid, and seminal fluid[117]; and their high haptocorrin content suggests a still unspecified role in relation to the gut microbiome and its abundant content of cobalamin and corrinoid analogues.

Typically, more than 70% of the cobalamin in plasma at any moment exists bound to haptocorrin, but this seeming preponderance is misleading because haptocorrin is cleared slowly from plasma ($t\frac{1}{2}$, 9.5 to 12 days), whereas transcobalamin ($t\frac{1}{2}$, only 90 minutes) carries 40 times as much cobalamin daily in plasma as haptocorrin does. Study of haptocorrin interactions with each of the many corrinoid analogs has been difficult, but levels of plasma analogues, whose sources are unknown, approach or exceed cobalamin levels.[123-125]

Absorption of Cobalamin

Cobalamin in food is almost entirely protein bound. It is released by the action of acid and pepsin in the stomach, where it binds to salivary or gastric haptocorrin in preference to IF when gastric pH is low (Fig. 10-4, *1*). In the duodenum, the haptocorrin-cobalamin complex from the stomach, and from bile, is broken down by pancreatic proteases, releasing cobalamin, which subsequently binds to IF (Fig. 10-4, *2*).[126] The IF-cobalamin complex binds to receptors in the apical brush border of enterocytes; the receptors are most abundant in the distal ileum (Fig. 10-4, *3*). The absorbed fraction varies inversely with the amount of ingested cobalamin. Absorption efficiency is more than 50% when the amount is 1 to 2 μg, which approximates some meal contents. High intake in a meal or supplement (e.g., 5 to 10 μg) exceeds the capacity of IF receptors and the excess free cobalamin is internalized only by nonspecific diffusion, a process with only approximately 1% efficiency.

The ileal receptor consists of two proteins, cubilin (the product of the *CUBN* gene on chromosome 10p12.1) and amnionless (the product of the *AMN* gene on chromosome 14q32), and has been named “cubam.”[127] Cubilin, a 460-kD protein that binds many ligands other than IF, such as transferrin and vitamin D–binding protein,[128] is anchored externally to the enterocyte membrane by amnionless, a 48-kD membrane-spanning protein.[129] Both components must be synthesized for cubam to be expressed at the cell surface.[130,131]

The IF-cobalamin complex is rapidly internalized by endocytosis after binding to cubam.[132] Cobalamin bound to transcobalamin (holotranscobalamin [holo-TC]) appears in the portal circulation 4 hours after ingestion. Although some studies have suggested that attachment of cobalamin to transcobalamin occurs within enterocytes after its release from IF,[133,134] studies in transgenic mice were consistent with export of free cobalamin from enterocytes by the ABCC1 (MRP1) membrane transporter with subsequent attachment to transcobalamin outside the enterocyte.[135]

Enterohepatic Recirculation

Approximately 1.5 μg of cobalamin and varying amounts of cobalamin analogues bound to haptocorrin are excreted in the bile daily.[102] Cross-species experiments in rabbits suggest that plasma haptocorrin uptake by asialoglycoprotein receptors on hepatocytes delivers cobalamin and analogues to bile,[136] but reservations exist and direct data are unavailable. Pancreatic proteases degrade the biliary haptocorrin (see Fig 10-4, *2*). Released cobalamin binds to IF and is reabsorbed in the ileum, whereas released analogues, unavailable to IF, are excreted in the feces.[137] This process salvages about two thirds of the cobalamin secreted in bile.[102]

Renal Cobalamin Reabsorption

The amount of cobalamin filtered daily is approximately 1.5 μg.[138] Little cobalamin is detected in urine under normal physiologic conditions because more than 99.8% is reabsorbed in the proximal tubules.[139] Cubilin and a second large multiligand receptor, megalin, are expressed in the proximal renal tubule,[140,141] where they reabsorb a variety of filtered proteins. Filtered holo-TC is reabsorbed by megalin.[64] Unbound cobalamin does not normally exist in plasma, but if it is introduced by parenteral injection, the filtered free cobalamin cannot be reabsorbed in the proximal tubule.

Cobalamin in Pregnancy

Cobalamin is efficiently transported across the placenta during pregnancy, and cobalamin concentration is higher in cord blood than in the maternal circulation, even in cases of maternal cobalamin insufficiency.[142-145] The mechanism of cobalamin transport remains poorly understood. Both cubilin and amnionless are expressed in the visceral yolk sac of rodents,[129,146] where they support uptake of nutrients (although not cobalamin).[146] It is not clear that the visceral yolk sac plays any role in nutrition of the postimplantation embryo in humans.[147] The transcobalamin receptor is present in human placenta, but its role in transplacental cobalamin uptake has not been studied.[148]

of homocysteine to form methionine, catalyzed by the cytoplasmic enzyme methionine synthase (EC 2.1.1.13). This reaction utilizes 5-methyltetrahydrofolate as methyl group donor and represents the point in cellular metabolism where cobalamin and folate metabolism intersect.[149] AdoCbl is required in the conversion of methylmalonyl-coenzyme A (CoA) to succinyl-CoA, which is catalyzed by the mitochondrial enzyme methylmalonyl-CoA mutase (EC 5.4.99.2).[150] In microorganisms, a variety of other enzymes utilize cobalamin for reactions that appear not to occur in mammalian cells.

Intracellular cobalamin concentrations are low, and many of the forms that are involved in metabolism are not stable in aqueous solution. This has led to the

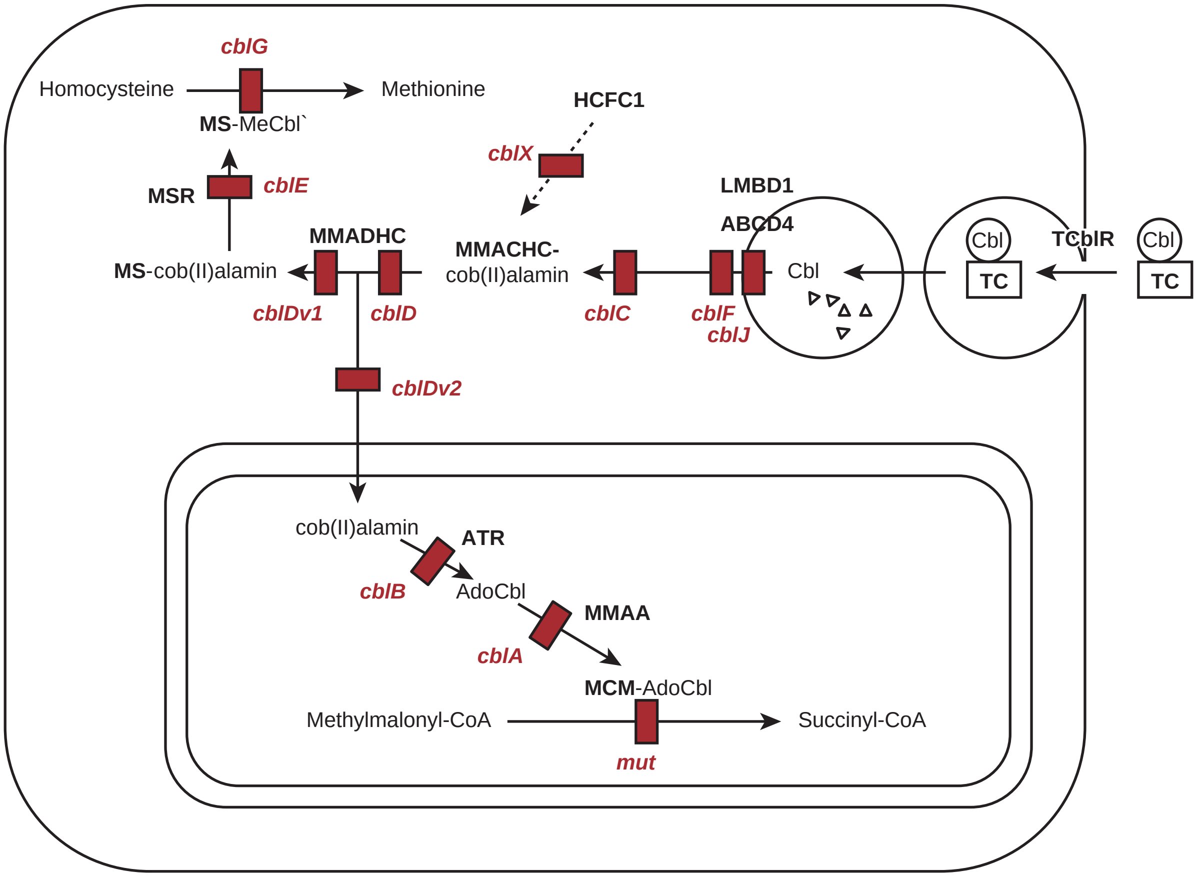

Figure 10-5 Scheme of cobalamin metabolism. The sites affected by methylmalonyl-CoA mutase deficiency *(mut)* and the inborn errors of cobalamin metabolism (*cblA-cblG, cblJ,* and *cblX*) are shown in *red*. The cblA disorder is caused by defects in the MMAA protein; the cblB disorder is caused by defects in the cob(I)alamin adenosyltransferase *(MMAB)* protein; the cblC disorder is caused by defects in the MMACHC protein; the cblD, cblD variant 1 *(cblDv1)*, and cblD variant 2 *(cblDv2)* disorders are caused by defects in the MMADHC protein; cblE disorder is caused by defects in the methionine synthase reductase *(MSR)* protein; cblG disorder is caused by defects in the methionine synthase *(MS)* protein; cblJ disorder is caused by mutations in the ABCD4 protein; cblX disorder is caused by mutations in the HCFC1 protein, and the mut disorder is caused by defects in methylmalonyl-CoA mutase *(MCM)*. suggestion that once cobalamin enters cellular metabolism it must be bound to protein at all times. Most cellular cobalamin exists bound to proteins, primarily methionine synthase in the cytoplasm and methylmalonyl-CoA mutase in the mitochondria.[151] It appears that cobalamin is not retained in cells unless it is bound to protein.

Uptake of circulating holo-TC is mediated by the transcobalamin receptor, which initiates endocytosis (see Figs. 10-4 and 10-5).[148] Transcobalamin is degraded in lysosomes, releasing cobalamin that is transferred across the lysosomal membrane by a process involving the lysosomal membrane proteins LMBD1 and ABCD4.[152,153] Once in the cytoplasm, cobalamin becomes associated with the molecular chaperone protein MMACHC, which catalyzes reduction of the central cobalt to the Co^{2+} state and removal of the upper axial ligand, if one is present.[154-156] Subsequently cobalamin may enter the mitochondria, where cobalamin is converted to AdoCbl by cobalamin adenosyltransferase and becomes associated with methylmalonyl-CoA mutase; a third protein, MMAA, is required for transfer of AdoCbl from adenosyltransferase to methylmalonyl-CoA mutase. Alternatively it can remain in the cytoplasm, where it becomes associated with methionine synthase and is converted to MeCbl.

Biochemical Effects of Cobalamin Deficiency

The biochemical consequences of cobalamin deficiency result from decreased activity of the cobalamin-dependent enzymes methionine synthase and methylmalonyl-CoA mutase. Decreased activity of methionine synthase results in elevated levels of its substrate, homocysteine, in the blood and excretion of homocystine in the urine. Decreased activity of methylmalonyl-CoA mutase results in accumulation of MMA in the blood and urine.

Methionine Metabolism

Methionine is an essential amino acid in humans. Methionine synthase remethylates the homocysteine generated from methionine during cellular metabolism, helping to maintain adequate methionine levels as well as preventing accumulation of potentially toxic homocysteine.

A cobalamin-independent enzyme, betaine : homocysteine methyltransferase, catalyzes homocysteine remethylation in liver,[157] but its activity is insufficient to prevent homocysteine accumulation when cobalamin-dependent methionine synthase activity is impaired. Methionine levels, however, often remain normal in cobalamin deficiency.

Cellular methionine may be utilized in protein synthesis or adenosylated to form S-adenosylmethionine, which acts as a methyl group donor in several dozen different transmethylation reactions, including methylation of DNA, which plays a role in regulation of gene expression, as well as methylation of RNA, lipids, proteins (including histones), neurotransmitters, and thiols.[158] These reactions generate the homocysteine that is acted on by methionine synthase. Homocysteine may also react with serine to form cystathionine, in a reaction catalyzed by cystathionine β-synthase.

Interaction of Folate and Cobalamin Metabolism

Deficiency of either folate or cobalamin, when substantial, produces megaloblastic anemia. The mechanisms leading to the anemia are complex. Folate deficiency directly affects the one-carbon substituted THF derivatives required for de novo thymidine and purine biosynthesis, resulting in abnormal DNA synthesis in bone marrow cells. The explanation for the hematologic similarity in cobalamin deficiency is believed to be the result of a secondary deficiency of these THF derivatives, best explained by the "methyl trap" hypothesis.[159,160] Because methionine synthase is the only reaction in human cells that can convert 5-methylTHF to THF, which can be utilized to form one-carbon substituted THF derivatives, and because the reaction that converts 5,10-methyleneTHF to 5-methyTHF is irreversible under physiologic conditions, cobalamin deficiency results in "trapping" of folate in the form of now unusable 5-methylTHF.[159,160]

MANIFESTATIONS OF DEFICIENCY

Overview of Folate and Cobalamin Deficiencies

Cobalamin and folate deficiencies can cause similar clinical manifestations. The most frequent manifestation, megaloblastic anemia, is identical in both deficiencies and is therefore described here for both. Indeed, the megaloblastic anemia caused by cobalamin deficiency may respond initially if folic acid is mistakenly given, especially in doses above the bare minimum,[161,162] although the hematologic improvement is often only partial and is rarely permanent. In contrast, the neurologic manifestations differ for the two vitamin deficiencies in adults, although cerebral and developmental consequences can be similar in infants with either deficiency. They will be discussed separately in sections devoted to each vitamin. Finally, the disorders causing each vitamin deficiency are very different. For all these reasons, rigorous differentiation between the two vitamin deficiencies must precede selection of the treatment.

Megaloblastic Anemia of Folate and Cobalamin Deficiencies

Three key features distinguish megaloblastic anemia from other anemias. First, there are the distinctive morphologic changes. Cells are not only macrocytic but their nuclei are also often larger. More specifically, a maturational nuclear-cytoplasmic dissociation defines megaloblastosis: the retarded chromatin condensation imparts an unusually immature, dispersed appearance to the nucleus, whereas the cytoplasm appears unremarkable (Fig. 10-6). Myeloid cells have megaloblastic nuclei that can be abnormally shaped and too large for their already large cells ("giant" metamyelocytes and band cells). Megaloblastic changes in mature neutrophils are characterized by nuclear hypersegmentation, which is usually defined by the presence of at least one six-lobed nucleus or suspected when several five-lobed neutrophils are seen in a blood smear. Lobe-count averages above 3.0 to 3.3 lobes per neutrophil also suggest megaloblastosis, but lobe counts are tedious and their subjectivity requires that each observer establishes a personal normal range. When florid, megaloblastic changes are dramatic and obvious in peripheral blood and marrow (see Fig. 10-6) but mild changes in the early stages of deficiency are easily missed.

Second, megaloblastic anemia is the prototype of ineffective hematopoiesis. Precursors are actively generated in the bone marrow, but they are defective. As the dyspoiesis worsens, precursors increasingly undergo cell death in the bone marrow and are phagocytosed before they can exit into the blood as reticulocytes. As erythropoietin secretion increases, the bone marrow becomes more hypercellular, but the reticulocyte count fails to increase. Evidence of the intense intramedullary cell death includes increases in markers of cell turnover, such as serum lactate dehydrogenase, and the consequences of increased hemoglobin breakdown, such as indirect hyperbilirubinemia and decreased or absent haptoglobin. The decreased survival of megaloblastic RBCs in the blood adds an element of peripheral hemolysis.

Finally, the megaloblastic process affects platelets and myeloid cells also. The anemia is the earliest and, for some time, the only cytopenia. However, as the megaloblastic anemia progresses, granulocyte and platelet counts decline, and pancytopenia can eventually mimic aplastic anemia. In rare cases, an erythroblastopenia mimicking pure red cell aplasia may be superimposed.[163,164]

Incidence and Evolution of Megaloblastic Anemia

Although the megaloblastic anemia is identical in folate and cobalamin deficiencies, its appearance after the dietary or malabsorptive onset of vitamin depletion in adults is measured in 2 to 3 months for folate deficiency[9] but in years for cobalamin deficiency[16] because of their disparate stores-to-daily intake ratios. The time course has not been documented as well in children, and onset may occur sooner in infants because of their smaller vitamin stores.

The earliest RBC changes are a rise in mean corpuscular hemoglobin followed shortly by a rise in mean corpuscular volume (MCV). These cell content and size changes precede the overt evidence of anemia,[9,165] in part because the early phases of the anemia involve declining RBC count but little change in blood hemoglobin and packed cell volume levels, which are compensated by the increasing RBC sizes and contents. Clinicians must pay

attention to changes in RBC indices regardless of hemoglobin and packed cell values. Although macrocytosis has many causes (Table 10-3), early megaloblastic anemia must be considered whenever a patient's MCV, even if still within the normal reference interval, has changed as little as 3 to 5 fL compared with a previous value.[165] The onset of macrocytosis can be documented even sooner by reticulocyte-specific indices of macrocytosis.[166] However, macrocytosis is sometimes masked if a microcytic disorder, most often iron deficiency or thalassemia trait, coexists. These combinations can produce normal, low, or high MCV, but the MCV is always higher than normal for that particular patient and it always decreases after the megaloblastic anemia is treated. The frequency of nonelevated MCV was 7% in one study of adults with pernicious anemia.[167] The macrocytosis typically features macroovalocytes, which suggest but are not specific to megaloblastic anemia. Anisocytosis and admixture of macrocytes with normocytes elevate the relative distribution of RBC width. As megaloblastic anemia progresses,

TABLE 10-3 Causes of Red Blood Cell Macrocytosis

Causative Conditions	Accompanying Hematologic Features
Megaloblastic Anemia	
Cobalamin deficiency Folate deficiency Antifol drugs (e.g., methotrexate) Cytotoxic drugs (e.g., hydroxyurea; 5-FU) Immunosuppressive drugs (e.g., azathioprine) Thiamine-responsive anemia Hereditary orotic aciduria	Megaloblastic changes, including hypersegmented neutrophils Macrocytosis can become severe Mild reticulocytopenia Pancytopenia (when the megaloblastic process is severe)
Disorders of Erythroid Production	
Aplastic anemia; PRCA; Blackfan-Diamond anemia Some sideroblastic anemias CDA; non-CDA dyserythropoiesis; Fanconi anemia Myelodysplasia; myeloproliferative diseases	Nonmegaloblastic Some disorders feature dyserythropoiesis and sometimes hyposegmented neutrophils Macrocytosis can often be severe (e.g., aplastic processes) Reticulocytopenia (often severe)
Reticulocytosis	
Chronic hemolytic anemia	Nonmegaloblastic; no hypersegmented neutrophils
Drugs and Toxins	
Alcohol abuse Some antiviral drugs (e.g., nucleoside RT inhibitors) Some anticonvulsant drugs	Mechanism of macrocytosis is often unknown No hypersegmented neutrophils
Nonhematologic Diseases	
Chronic liver diseases Hypothyroidism Copper deficiency	Nonmegaloblastic; no hypersegmented neutrophils Macrocytes are rarely oval
Artifacts	
RBC clumping by cold agglutinins; some warm RBC antibodies Severe hyperglycemia Hyponatremia	Nonmegaloblastic; no hypersegmented neutrophils Disparity between high MCV and normal morphologic examination

CDA, Congenital dyserythropoietic anemia; *MCV,* mean corpuscular volume; *PRCA,* pure red cell aplasia; *RBC,* red blood cells; *RT,* reverse transcriptase; *5-FU,* 5-fluorouracil.

poikilocytosis, including teardrop cells, becomes prominent. With severe anemia, circulating nucleated erythroid precursors, Cabot rings, and Howell Jolly bodies can appear.

The other early manifestation preceding anemia is nuclear hypersegmentation in neutrophils (see Fig. 10-6).[9,16,168] It is also a much more specific feature of megaloblastic change than is macrocytosis. Unexplained hypersegmentation[169] and other dysplastic granulocytic changes[170] may also follow high-dose corticosteroid treatment of idiopathic thrombocytopenic purpura, however. The mechanism of hypersegmentation is unknown.

Neutropenia and thrombocytopenia are late features, appearing only infrequently before the hemoglobin level decreases below 10 g/dL; cytopenias that accompany mild anemia usually have independent explanations. The pancytopenia can ultimately become severe enough to mimic severe aplastic anemia. The two can be differentiated by the serum lactate dehydrogenase elevation (often exceeding 1000 units) and indirect hyperbilirubinemia in megaloblastic anemia.

Macrocytic anemia, the most common clinical feature of cobalamin or folate deficiency in adults, can be mild but it affects more than 70% of patients with clinically expressed deficiency, such as in pernicious anemia[171,172]; comparable data are not available in children. The reason why some patients with pernicious anemia do not develop anemia, even if they may have mild megaloblastic changes in the bone marrow that often escape detection, is unknown. Interestingly, a roughly inverse relationship between the severity of the hematologic and neurologic expressions has been described[173,174] and the dominant expression tends to dominate again with relapses.[173,175,176] A comparison of predominantly hematologically versus neurologically affected patients showed the predominantly anemic patients to have lower plasma glutathione, S-adenosylmethionine, cysteine, and folate levels, whereas a higher cysteine level was the most significant predictor of neurologic dysfunction.[174]

Biochemistry of Megaloblastic Anemia

In deficiency of either folate or cobalamin, all dividing cells, especially bone marrow precursors and epithelial cells, show megaloblastic changes. MethyleneTHF, which mediates the methylation of deoxyuridylate to deoxythymidylate (see Fig. 10-2), is directly depleted in folate deficiency but can also be secondarily depleted in cobalamin deficiency, as best explained by the methylTHF trap hypothesis. Nevertheless, de novo thymidylate synthesis disruption, although necessary, may not by itself suffice to produce megaloblastic changes.[177-179]

The misincorporation of excess uracil into DNA may exceed the capacity of excision repair, leading to single-strand breaks as well as occasional double-strand breaks. The latter may help explain the nuclear defects.[180] Arrest at various stages of interphase occurs in megaloblastic precursors even while maturation proceeds,[181] but the details are still unclear.

Mistaken folic acid therapy for clinically expressed cobalamin deficiency can bypass the methylTHF trap and improve the megaloblastic anemia.[161,162] However, the response is often only partial and is usually impermanent. Concerns exist that neurologic manifestations may progress in the meantime and become irreversible as the cobalamin deficiency remains unrecognized and untreated. Systematic evidence is unavailable, and mistaken folic acid therapy may occasionally even improve neurologic status.[162] However, ethical constraints prevent prospective studies and it is agreed that folate treatment must be avoided in cobalamin deficiency.[16] These concerns prompted restriction of folic acid doses, as well as folic acid–fortified food intake, to 1 mg/day or less.

Ancillary Features of Megaloblastic Anemia

The ineffective hematopoiesis of megaloblastic anemia disrupts iron metabolism, raising serum iron, transferrin receptor, and ferritin levels, along with sideroblast counts and the ferritin content in erythroid precursors and macrophages.[182,183] These changes can occur even in the presence of a coexisting iron deficiency, which may remain hidden until the ineffective erythropoiesis is corrected.[16] Severe megaloblastic anemia also has a still unexplained element of intravascular hemolysis. Membrane protein changes, including spectrin, have been described in megaloblastic RBCs, but their impact is unknown.

Nonhematologic Manifestations of Cobalamin Deficiency

Neurologic Manifestations

Neurologic dysfunction is common, but its frequency is unclear because neurologic disease is not easily quantified, unlike the probably more common hematologic abnormalities. Whereas 13% to 27% of adults with pernicious anemia have had neurologic symptoms without anemia,[171,172] the proportion with anemia without neurologic abnormalities is higher.

The classic neurologic manifestations feature a symmetric myelopathy, largely limited to the posterior and lateral columns ("subacute combined degeneration") and neuropathy.[184,185] The myelopathy typically begins with sensory and proprioceptive changes in the feet and ascends at variable rates to involve hands and arms as deficiency progresses. If not caught early, the changes may become partially or completely irreversible and can evolve to spasticity, ataxia, and incontinence. Other manifestations include mental changes of varying severity (mild electroencephalographic abnormalities can occur even without overt symptoms), autonomic dysfunction, and, rarely, optic neuritis.[16,173,186-188]

In newborns and infants, deficiency and its manifestations appear sooner than in adults because of the smaller storage reserves, because hereditary defects of cellular metabolism often act more quickly and directly on tissues than dietary or malabsorptive disorders, and most especially because the developing nervous system is at greater risk than the mature nervous system. Often, the manifestations include impaired growth and development. Thus the neurologic changes common to older children and adults are overshadowed in infants by failure to thrive, poor brain growth, developmental delay, seizures, motor retardation, and movement disorders[189-192]; the movement disorders, which sometimes increase transiently after cobalamin therapy, can be mistaken for seizures.[193] The diagnostic connection to cobalamin deficiency is often diverted or delayed for months and, even in nonhereditary disorders, developmental and neurologic residua may persist long after therapy.[191]

The mechanisms responsible for the demyelination in the central nervous system, followed by axonal degeneration and gliosis, in clinical cobalamin deficiency, or for the nondemyelinative peripheral neuropathy, are unknown.[184,185] Still unproven etiologic hypotheses for neurologic dysfunction have included abnormal myelin lipid synthesis because of abnormal propionate metabolism, defective neurotransmitter metabolism, corrinoid analogue accumulation, and cytokine abnormalities. Evidence from the clinical patterns in diverse *cbl* mutations and other findings favors a central, but perhaps not sufficient, role for methionine synthase inactivation, which disrupts methionine metabolism and S-adenosylmethionine–dependent methylation reactions. However, folate deficiency, which also inactivates methionine synthase, rarely produces neurologic abnormalities of comparable severity to cobalamin deficiency in adults,[16] although hereditary disorders of folate metabolism in children often do.

Other Clinical Manifestations

Cobalamin deficiency can cause atrophic glossitis and stomatitis, which can be painful.[16] Somewhat similar changes occur in folate deficiency, but the oral changes respond only to the specific vitamin whose deficiency caused them. Unexplained weight loss, sometimes substantial, can occur with severe cobalamin deficiency in adults and children, and it reverses after cobalamin therapy. Infants sometimes feature prominent gastrointestinal dysfunction, such as diarrhea. Severely deficient infants can also present with recurrent infections that mimic immune deficiency states.

Young patients with severe deficiency, especially nonwhites, sometimes display pigmentary changes that reverse with cobalamin therapy: skin hyperpigmentation that overlies joints, dark hair that turns a light reddish hue, or blue discoloration of fingernails and toenails.[189,194-196] The pigmentary changes should not be confused with the unrelated, irreversible autoimmune vitiligo that occasionally coexists with pernicious anemia. Adults with pernicious anemia display reduced levels of osteoblastic proteins, such as osteocalcin and bone alkaline phosphatase, which respond to cobalamin.[197] Reports of clinical bone complications in adults await systematic proof. Bone effects have not been studied in children.

Subclinical Cobalamin Deficiency

Unexplained low serum cobalamin levels that were unaccompanied by clinical manifestations, did not progress to clinical manifestations, and displayed no clinical benefits after cobalamin treatment were originally regarded as spurious. However, biochemical studies established that some of these represented mild metabolic cobalamin insufficiency and, unlike more than 90% of cases with megaloblastic anemia and other clinical dysfunction, they were rarely associated with the loss of IF or IF-mediated absorption by ileal cells.[178,179] This often purely biochemical abnormality became known as "subclinical cobalamin deficiency." As accurate, sensitive, automated tests of cobalamin metabolism, such as MMA and tHcy, became widely available, epidemiologic studies established that subclinical deficiency affected many adults, especially the elderly, and indeed was several times as common as pernicious anemia and other clinical deficiency states.[198,199] The causes of subclinical deficiency are often unknown, but a plurality of 30% to 50% of patients have malabsorption of food-bound cobalamin, which is usually associated with chronic gastritis, achlorhydria, or gastric surgery.[200] Because poor dietary intake alone cannot usually deplete cobalamin stores sufficiently in adults and older children to cause clinical deficiency, most vegetarians, especially adults, display only subclinical deficiency.

The health consequences of subclinical cobalamin deficiency are unknown, and progression to clinically expressed deficiency seems infrequent.[201] In the absence of compelling data from randomized clinical trials, the benefits of intervention to reverse isolated biochemical changes of still unproven likelihood of progression to clinical deficiency remain unsettled.[202,203,204]

Subclinical deficiency has not been studied in children and was believed rare. However, a transient, purely metabolic cobalamin deficiency affecting many normal infants in the first year of life has been documented in Scandinavia[108,205,206] and is discussed in the section on dietary cobalamin insufficiency. The metabolic phenomenon must also be borne in mind when using current cobalamin status–related reference intervals in infants, and hematologists and geneticists must consider this transient phenomenon when evaluating MMA elevations in infants.

Nonhematologic Manifestations of Folate Deficiency

Neurologic Manifestations

Folate deficiency in adults does not cause the severe demyelinative myelopathy characteristic of cobalamin deficiency. Forgetfulness and mood changes, such as irritability, have been described,[9,207] as has neuropathy.[208] However, their attribution and specificity remain unsettled because folate deficiency is often not an isolated deficiency. Nevertheless, the neurologic consequences can be severe in some folate deficiency disorders in newborns and infants. Children with hereditary folate malabsorption, cerebral folate deficiency, and severe MTHFR deficiency (the last two of which do not display megaloblastic anemia) often have seizures, microcephaly, developmental delay, mental retardation, and myelopathy.

Other Clinical Manifestations

Mucosal changes of the tongue and mouth can sometimes resemble those of cobalamin and other deficiencies. However, because folate deficiency is often part of a broader nutritional inadequacy, responsiveness specifically to folic acid provides the best proof of causation.

Subclinical Folate Deficiency

Subclinical deficiency, definable as isolated abnormalities of folate and tHcy levels without megaloblastic changes or other clinical expressions of folate deficiency, has not been studied or defined as formally as subclinical cobalamin deficiency. Certain subpopulations are at special risk because of marginal dietary folate intake, increased folate requirements, or both, such as children (including adolescents), pregnant women, people with homozygosity for common polymorphisms of the *MTHFR* gene, and alcoholics. Although not studied formally, subclinical folate deficiency is almost certainly more common than clinically expressed deficiency.

Countries such as the United States and Canada have mandated fortification of cereal and grain products with folic acid to reduce NTD risks. This policy has nearly eliminated clinical folate deficiency in the general populations, sharply reduced the prevalence of isolated low folate levels, and lowered tHcy levels.[23,209,210] The influence of folate status on hyperhomocysteinemia and on NTDs is clear, but the record on vascular disease, cancer, and cognitive decline in the elderly is mixed or ambiguous, as discussed elsewhere in the chapter. It merits emphasis that many of the public health risks, including NTDs, have generally been associated with subclinical folate deficiency and possible genetic or acquired alterations of folate demand or utilization, rather than with clinically overt maternal folate deficiency.

DIAGNOSIS OF DEFICIENCY

Once detected, megaloblastic anemia and other clinical expressions of deficiency require confirmation that a vitamin deficiency is responsible and differentiation between folate and cobalamin deficiency. Measuring vitamin levels directly, the usual way to accomplish this, must be done before instituting therapy. Measuring metabolic biomarkers of vitamin adequacy, such as MMA and tHcy, is valuable whenever vitamin levels or the clinical picture are equivocal. Both metabolic biomarkers must be tested whenever a hereditary metabolic disorder that may not depress serum vitamin levels is suspected.

Biochemical tests are now accurate, automated, widely available, and generally quite sensitive, especially when the deficiency is advanced enough to have produced macrocytic anemia or neurologic symptoms. However, none of the tests qualifies as a diagnostic "gold standard," largely because all of them lack the requisite diagnostic specificity for either folate or cobalamin deficiency. The innate specificity shortcomings have been exacerbated by inconsistent and sometimes controversial selections of cutpoints that demarcate "normal" from "abnormal" results, choices that have major, but often hidden, impact.[211] Clinical judgment must always take precedence whenever a test result conflicts with the clinical picture. Pediatricians must also be aware that ranges of biochemical biomarker values appear to fluctuate during childhood, especially in early infancy and perhaps adolescence, where the fluctuations may sometimes hide subclinical deficiency rather than reflecting normal physiologic variability (Table 10-4).[205,212]

The biochemical tests can also help evaluate the response to therapy.[16,202] Measuring MMA or tHcy, depending on the deficiency in question, 1 to 2 weeks after therapy begins is useful because these metabolic intermediates improve only if therapy was effective. In contrast, serum vitamin content (i.e., cobalamin, holo-TC, and folate levels) rises automatically with vitamin therapy irrespective of therapeutic effectiveness. The timing of blood sampling relative to the most recent dose also determines the degree of automatic vitamin content change.

TABLE 10-4 Median (and Interquartile Range) Values for Plasma Cobalamin, Folate, Homocysteine, and Methylmalonic Acid Throughout Normal Childhood

Age	Cobalamin (ng/L)	Folate (μg/L)	tHcy (μmol/L)	MMA (nmol/L)
4 days	425 (322-634)	11.9 (9.0-16.0)	6.2 (5.0-7.5)	290 (240-390)
6 wk to 6 mo	294 (199-393)*	13.9 (9.4-19.1)*	7.5 (6.1-9.2)*	780 (360-1510)*
1 to 10 yr	747 (618-925)	6.6 (5.3-9.3)	5.2 (4.7-6.0)	130 (110-170)
10.5 to 15 yr	591 (400-717)	5.3 (4.0-6.7)	6.5 (5.7-7.8)	170 (130-220)
15.5 to 19 yr	500 (398-612)	4.3 (3.4-5.6)	7.8 (6.6-9.1)	140 (120-180)

Modified from Bjorke Monsen AL, Refsum H, Markestad T, et al: Cobalamin status and its biochemical markers methylmalonic acid and homocysteine in different age groups from 4 days to 19 years. Clin Chem *49:2067–2075, 2003.*

MMA, Serum methylmalonic acid; *tHcy,* plasma total homocysteine.

*These values reflect distortions by the high frequency of transient subclinical cobalamin deficiency in breastfed infants. Breastmilk, although relatively rich in folate, can be limited in cobalamin content. (Cow's milk is rich in cobalamin.)

Vitamin Content Assays

Cobalamin Assay

Serum cobalamin measurement, although problematic, is the traditional test of choice for diagnosing cobalamin deficiency. Microbiologic assay, based on growth of cobalamin-dependent microbes on exposure to the test serum, is unavailable outside select reference and research laboratories. Clinical laboratories, which adopted isotopic, competitive-binding assays in the 1970s, have come to rely almost exclusively on automated, competitive-binding, chemiluminescence-based immunoassays since the late 1990s. Most laboratories define subnormal levels as below 200 or 250 ng/L (150 or 200 pmol/L). However, some authors raised cutpoints to 300 to 350 ng/L to capture nearly all elderly patients with otherwise isolated, mild MMA and tHcy elevations.[198,213] This redefined reference interval led to claims that 40% or more of the elderly have cobalamin deficiency, but most of the redefined cases lacked clinical or metabolic evidence of deficiency,[214] in part because abnormal MMA and tHcy themselves lack specificity.[211] The cutpoint expansion worsened the already poor diagnostic specificity of a low cobalamin level.[202] Most laboratories continue to use the 150-ng/L cutpoint in children, but levels, as shown in Table 10-4, fluctuate during childhood, especially in early infancy,[205,212,215] when cobalamin stores are small relative to intake and when maternal influences dominate.

Adults have many causes of falsely low cobalamin levels, including levels less than 100 ng/L sometimes. A major cause is pregnancy, with levels decreasing below 150 ng/L in almost half of women by the last trimester.[16,216,217] The explanation is uncertain but may reflect maternofetal cobalamin transfer in part. Metabolic or clinical evidence of deficiency is rare, and cobalamin treatment is unnecessary. The levels become normal spontaneously a few weeks after delivery.

Folate deficiency often decreases serum cobalamin levels also, which become subnormal in 10% of patients.[16] Folate therapy restores cobalamin levels to normal, but alertness is warranted because occasional patients, especially those with gastrointestinal disease, have concurrent deficiencies of both vitamins. Interestingly, hepatic cobalamin content is also somewhat low in folate deficiency.[218] Other conditions associated with unexplained low cobalamin levels include oral contraceptive use, obesity, infection with human immunodeficiency virus, and multiple myeloma.[219-222] Falsely low cobalamin levels also accompany hereditary or, less often, acquired deficiency of haptocorrin.[223] Finally, the likelihood of falsely subnormal cobalamin levels rises sharply when overly liberal cutpoints, such as 300 ng/L, are applied.[211]

Elevated cobalamin levels are more common than low levels in adults[224] and can occasionally hide a coexisting cobalamin deficiency.[225] Examples relevant to children include defects in cellular cobalamin metabolism, in which serum cobalamin (and holo-TC) levels remain normal or increase; these metabolic defects can be hereditary or acquired, as with nitrous oxide toxicity. A troubling malfunction peculiar to modern chemiluminescence-based cobalamin assays often causes spuriously normal (or elevated) levels in IF antibody–positive sera from cobalamin-deficient patients with pernicious anemia.[226,227] Children with the juvenile form of pernicious anemia are often antibody positive and thus probably susceptible to the assay error. Renal failure can also cause spuriously elevated serum cobalamin.[224] Race affects cobalamin levels; blacks have significantly higher levels at all ages than whites or Asians.[228] Homozygosity for a common polymorphism of the *FUT2* gene, affecting fucosylation, also causes slightly higher cobalamin levels.[229,230] Finally, clinicians faced with unexpectedly normal or high cobalamin levels must consider recent cobalamin therapy as a possible cause.

Red cell cobalamin is rarely measured today because levels depend largely on the proportion of reticulocytes, which are rich in cobalamin, rendering results unreliable.

Serum Holotranscobalamin Assay

Holo-TC, the cobalamin fraction attached to transcobalamin, contains 10% to 30% of the total cobalamin in plasma at any moment in time (although the very high turnover of transcobalamin obscures the fact that transcobalamin carries much more cobalamin daily than haptocorrin does). Because holo-TC is the only cobalamin fraction that is available for delivery to cells, it is regarded by some authors to be a more reliable indicator of cobalamin status than serum (total) cobalamin.[231] However, head-to-head receiver operator characteristics-based comparisons have shown holo-TC to be only marginally superior to total cobalamin (areas under the curves of 0.66 to 0.90 vs. 0.60 to 0.86 in six studies) in recognizing deficiency defined by MMA levels[232]; its specificity and positive predictive value are as poor as that of serum total cobalamin,[233,234] but the causes await careful study. A recent study reported low holo-TC levels in folate-deficient patients also[235]; as noted earlier in this chapter, serum total cobalamin and hepatic cobalamin levels are also low in folate deficiency. Holo-TC testing also suffers from considerable cutpoint variability.[232]

It is unclear whether the 90-minute half-life of plasma holo-TC leaves its levels too susceptible to transient changes in cobalamin flow from the gut to reliably reflect cobalamin stores and status, which change slowly. Evidence of relatively decreased holo-TC levels in patients with pernicious anemia in clinical and metabolic remission[236] suggests that daily absorption flux, not just cobalamin adequacy, influence holo-TC levels, whose turnover is so great. More studies are needed to identify relevant influences that explain the poor specificity of low holo-TC levels.

Serum Folate Assay

As with cobalamin, folate testing began with microbiologic assay and, after 25 years of isotopic competitive-binding assay, is currently done by automated chemiluminescent assay. Current cutpoints approximate 2.5 to 3.0 μg/L (5.7 to 6.8 nmol/L) in adults. Normal levels fluctuate during childhood, with higher levels in early infancy that decline thereafter, reaching low-normal values in adolescence (see Table 10-4).

Serum folate has high sensitivity for folate deficiency. However, specificity is poorer because the serum levels disproportionately reflect recently ingested and absorbed folate. Transiently poor intake lowers the serum levels within 1 to 3 weeks, long before actual deficiency of stores.[9,16]

A relevant cause of serum folate elevation is clinically expressed cobalamin deficiency, such as pernicious anemia, which causes RBC methylTHF to increase; however, the poor retention of methylTHF in RBC rapidly produces low RBC folate, along with high serum folate levels in 20% of cases.[16] It is unknown if mild or subclinical cobalamin deficiency affects folate levels similarly. Dietary fortification with folic acid in the United States raised serum folate levels,[209,237,238] and the frequency of levels below 3 μg/L decreased from 18% to 0.2%.[238] Plasma tHcy levels improved commensurately.[210]

Red Blood Cell Folate Assay

RBC folate content does not change after the reticulocyte stage and is thus less susceptible to short-term fluctuation than serum folate.[16,239] The RBC level is a 120-day reflection of folate status, not a transient 1- to 3-week snapshot. However, RBC folate is subnormal in 60% of patients with pernicious anemia because the methylTHF accumulation caused by the folate trap in cobalamin deficiency is poorly retained by the RBC.[16] Measuring serum folate, which is low in folate deficiency but high in cobalamin deficiency, can resolve the confusion. Other distortions of RBC folate content include blood transfusion, iron deficiency (which elevates RBC folate), and hemolytic anemia (reticulocytes have increased folate content). The choice between RBC and serum folate testing has generated disagreement,[240,241] and clinicians should base their choice on the diagnostic question being asked.

Cutpoint selection has varied considerably. In adults, RBC folate cutpoints defined by megaloblastic anemia were set at 140 or 150 μg/L[120] but later cutpoints based on metabolic criteria approximated 190 to 200 μg/L. A study of normal Scandinavian children identified age-related variation, with highest RBC folate in newborns (breastmilk has high folate content) and a steady decline from the first 6 months to the lowest levels in adolescents.[205]

Biomarkers of Metabolic Status

Methylmalonic Acid Assay

Current gas chromatography/high-performance liquid chromatography/mass spectrometry methods are accurate and, with automation, serum MMA assay has become increasingly available; urine assays are done less often. Serum MMA elevation has 98% sensitivity for clinically expressed cobalamin deficiency,[242-244] although its sensitivity in subclinical deficiency is unknown because no diagnostic gold standard exists for comparison.[232] Being the only test unaffected by folate deficiency, MMA assay is widely considered the best available metabolic test for cobalamin deficiency, but its specificity is limited (Table 10-5).[211,232,245] A survey in adults found that cobalamin status, renal status (MMA values correlate directly with serum creatinine, even within the normal range), age, and sex explained only 16% of the MMA level.[245] Creatinine is the major known confounder and should be measured when MMA is elevated.

Most laboratories use a cutpoint approximating 270 nmol/L (0.27 μmol/L) in adults, but cutpoint selection has varied between 221 to more than 400 nmol/L, with predictably inverse impact on the frequency of cobalamin "deficiency."[232,246] MMA reference intervals have been lower in children than in adults, but they fluctuate in early infancy (see Table 10-4). Many infants display transient MMA elevations, now believed to reflect a mild subclinical cobalamin deficiency among exclusively breastfed infants[108,205,206,212] but which had distorted pediatric MMA reference intervals for years.

MMA is also an effective, albeit more expensive, biochemical tool for monitoring response in cobalamin deficiency. Levels begin to decrease several days after cobalamin therapy (but not after folate therapy) and become normal within 2 to 3 weeks.[243]

TABLE 10-5 Causes of Elevated Homocysteine and Methylmalonic Acid Levels, with Emphasis on Conditions Encountered in Children

MM-CoA, Methylmalonyl coenzyme A; *MMA,* methylmalonic acid; *tHcy;* total homocysteine.

[*] Some cobalamin-deficient patients may have only MMA or tHcy elevation, not both, for unknown reasons; this is seen especially often in mild subclinical cobalamin deficiency.

[†] The tHcy elevation in infancy presumably caused by exclusive breastfeeding is milder than the MMA elevation, and levels are often high normal rather than elevated.

[‡] See sections on cobalamin mutations for the specific entities.

[§] Folate deficiency and tHcy elevation may not become expressed in some cases unless dietary intake is also limited.

[‖] tHcy levels are normal in most cases, but abnormality can be elicited by methionine loading.

Plasma Total Homocysteine Assay

Plasma tHcy elevation is highly sensitive for folate deficiency and nearly as sensitive as MMA elevation for cobalamin deficiency.[243,244] The degree of tHcy elevation in severe cobalamin or folate deficiency can mimic that seen in severe cystathionine β-synthase deficiency.[247] However, inability of tHcy to distinguish between folate and cobalamin deficiencies limits its diagnostic utility. The many influences that elevate tHcy include serum creatinine, age, gender, and, uniquely among tests of cobalamin and folate status, preanalytic influences, especially using serum instead of plasma and failing to separate plasma from cells quickly (see Table 10-5).[247] Cutpoint selection also affects diagnostic reliability. Reference intervals for tHcy fluctuate during childhood,[205] peaking during the transient subclinical cobalamin deficiency affecting many healthy infants (see Table 10-4). A second, mild tHcy elevation occurs during adolescence, presumably reflecting a downward trend in folate status.[205,210]

The high sensitivity of tHcy assay for cobalamin and folate deficiency and its relative inexpensiveness provide two valuable diagnostic roles: a normal tHcy level largely rules out the presence of clinically relevant folate deficiency, and the tHcy assay is the most cost-effective metabolic monitor of response of either cobalamin or folate deficiency to specific therapy. tHcy begins to decrease within a week and becomes normal within 1 to 3 weeks.[248]

Miscellaneous Tests

Plasma cysteine increases along with tHcy in cobalamin and folate deficiencies, but methionine levels show little change.[174,248] Measuring 2-methylcitric acid[249] provides little diagnostic advantage over MMA measurement. The deoxyuridine suppression test, an older, indirect means of evaluating thymidylate adequacy, allows diagnosis of folate and cobalamin deficiencies at the cellular level when specific vitamins are added to cells in vitro[178,250,251] but requires bone marrow cells and is labor intensive. Formiminoglutamic acid excretion lacks specificity and is no longer used diagnostically.

Response to a Trial of Specific Therapy

Objective evaluation of response to either cobalamin or folic acid provides the ultimate diagnostic confirmation.[16,202] It is especially helpful in patients whose diagnostic results conflict with clinical judgment or are inconclusive. A convincing therapeutic trial requires giving the suspected vitamin alone, preferably as a single dose, and giving enough vitamin to produce a response but not so much that therapeutic specificity is lost. Approximate suggestions in older children and adults include 10 to 50 μg of cobalamin or 100 μg of folic acid; parenteral injection is advisable if malabsorption is present or suspected. Trial recommendations are less uniform in young children and must be tailored by size, age, and the nature of suspected diseases.

If anemia was present, reticulocytosis should begin within 3 days and peak at 7 days. Potential sources of diagnostic error include using more than one hematinic or using large doses of folic acid, which may elicit a hematologic response even in patients with cobalamin deficiency. With the correct vitamin, tHcy or MMA levels begin to improve within a week and become fully normal within 2 to 3 weeks, except in some severe metabolic disorders[242,248]; neither metabolite improves if the wrong vitamin is given. Serum vitamin and holo-TC have little monitoring value because vitamin content almost always increases, even when therapy is ineffective.

ACQUIRED CAUSES OF COBALAMIN DEFICIENCY

The diagnostic task does not end with identifying the responsible vitamin deficiency. Many management and prognostic decisions require knowing the underlying disorder. This section discusses the acquired causes of cobalamin deficiency, generally following the sequence of events from intake to cellular metabolism (see Fig. 10-4). Hereditary disorders will be discussed in detail in separate sections.

An important distinction between folate and cobalamin physiologies helps explain a major difference between the two deficiencies' frequencies and expressions. The two vitamins' body stores–to–daily intake ratios are strikingly disparate, especially in older children and adults. This difference means that adult folate stores can become depleted sufficiently within 2 to 3 months to cause clinical deficiency whereas cobalamin store depletion in adults requires several years.

A comparison gleaned from Chanarin's summaries in 1979 of the scarce data of stores in infants[16] and the Institute of Medicine's recent estimates of daily intake requirements[14,99] provides a perspective on the reduced cushions for dietary adequacy in infants. The infants' daily cobalamin intake requirements are one fifth of that for adults but stores are only one fiftieth as great in infants as in adults. For folate, the infants' daily requirements are one fifth that for adults, whereas stores are one twelfth as great as in adults. These estimates suggest that infants' stores, while reduced for folate, may be especially precarious for cobalamin.

The underlying causes of cobalamin deficiency are listed in Box 10-1. In adults and older children, clinically expressed deficiency usually occurs only if the highly specific absorption system fails and if the failure is both substantial and persistent enough to nearly exhaust stores. Therefore severe malabsorption, the most common form being pernicious anemia (loss of IF), accounts for more than 90% of clinical cases of deficiency in adults and older children[244] but not in newborns and infants.

Box 10-1 Causes of Cobalamin Deficiency*

- Inadequate nutrition
  - Strict vegetarians and vegans
  - Exclusively breastfed infants of cobalamin-deficient mothers
  - Exclusively breastfed infants of mothers with normal cobalamin status
  - Exclusive reliance on goat's milk
- Defective absorption
  - Inadequate gastric intrinsic factor
    - Acquired pernicious anemia (adult and juvenile)
    - Pernicious anemia associated with agammaglobulinemia or common variable immunodeficiency
    - Hereditary intrinsic factor deficiency
    - Total gastrectomy
  - Food-bound cobalamin malabsorption
    - Chronic gastritis (without loss of intrinsic factor)
    - Gastric surgery (e.g., partial gastrectomy; bariatric surgery)
    - Drugs that inhibit gastric acid secretion
  - Disease of the small intestine:
    - Surgical resection or bypass of the terminal ileum†
    - Bacterial overgrowth in the intestine (motility disorders, strictures, etc.)
    - Diseases involving the ileum†
      - Tropical sprue
      - Regional enteritis (Crohn disease)†
      - Competition by parasites (fish tapeworm)
    - Imerslund-Gräsbeck syndrome
- Defects in transport and delivery to cells‡
  - Transcobalamin deficiency
- Defects in cellular metabolism
  - Nitrous oxide toxicity
    - Chronic ("recreational") abuse
    - Anesthetic exposure in the presence of unrecognized pernicious anemia, veganism, etc.
  - Hereditary metabolic disorders
    - Cbl disorders§
- Disorders of uncertain relevance
  - Pancreatic insufficiency ; cystic fibrosis
  - Miscellaneous drugs affecting absorption by unknown mechanisms¶

*Red type indicates progressive disorders that usually cause clinically expressed cobalamin deficiency, often of malabsorptive origin.

Normal type indicates slowly progressive or nonprogressive disorders that usually cause only mild, isolated biochemical changes (subclinical deficiency).

Blue type indicates disorders that can cause either clinical or subclinical cobalamin deficiencies.

†Development of clinical deficiency depends on the extent of ileal involvement.

‡Haptocorrin (transcobalamin I) deficiency is not included in this box because it causes low cobalamin levels but does not affect cobalamin uptake by cells or cause cobalamin deficiency.

§Patients with cblC, cblD, cblE, cblF, cblG, and cblJ diseases have megaloblastic anemia, but patients with the other cbl disorders do not.

Intrinsic factor–dependent malabsorption is frequent but is surprisingly seldom translated into cobalamin deficiency or clinical signs of deficiency.

¶Many drugs, such as colchicine and paraaminosalicylic acid, inhibit intestinal absorption of cobalamin, but they are too infrequently taken long enough or consistently enough to deplete cobalamin stores and cause cobalamin deficiency.

Dietary Cobalamin Insufficiency

Dietary Insufficiency in Adults and Older Children

A narrowly focused cobalamin inadequacy, ranging from strict veganism to mild ovolactovegetarianism, in which dairy products and eggs are consumed, can produce cobalamin deficiency. However, the process of depleting 80% of the very high storage cushion found in adults and older children to induce clinical deficiency with megaloblastic anemia or myeloneuropathy[16,99] takes years and requires uninterrupted dietary restriction. Indeed, depletion takes longer than in pernicious anemia and other malabsorptive diseases because vegetarians continue to reabsorb biliary cobalamin normally. Subclinical deficiency limited to mild abnormalities of serum cobalamin and MMA levels can be seen, but clinical deficiency is surprisingly infrequent, even in strict vegans, unless other events, such as malabsorption or increased metabolic requirements, supervene.[252]

Dietary Insufficiency in Infants

Intake adequacy poses greater problems in infants than in older children. The much reduced stores–to–daily intake ratio in newborns requires expansion during infancy and the demands of growth and development. Despite maternofetal transfer of cobalamin that favors the fetus even when mothers have borderline cobalamin status,[16] the small cobalamin stores at birth must then be expanded to accommodate the demands of growth, neurologic maturation, and cognitive development. In early infancy, much (and often, all) of the diet consists of breastmilk. The severity and duration of any maternal restrictions, whether in cobalamin transfer to the fetus, breastfeeding, or both, can influence the degree of deficiency in the infant. Indeed, maternal cobalamin status at delivery correlates significantly with the infant's status not just at birth but also 6 months later.[253] Breastmilk cobalamin content is also influenced by maternal status.

TABLE 10-6 Relationships between Breastmilk Cobalamin Content and Maternal and Infant Cobalamin Status*

	Birth/2 wk Postpartum	At 4 mo	At 9 mo
Mean breast hindmilk	561 (760)	214 (290)	325 (440)
Cobalamin concentration (n = 25)			
Paired mean plasma			
Cobalamin levels:			
Mothers (n = 60)	295 (400)	288 (390)	310 (420)
Infants (n = 60)	325 (440)	177 (240)	236 (320)
Mean serum MMA			
Levels (nmol/L):			
Mothers (n = 60)	180	170	160
Infants (n = 28)	270	440	240

Data modified from Greibe E, Lildballe DL, Streym S, et al: Cobalamin and haptocorrin in human milk and cobalamin-related variables in mother and child: a 9-mo longitudinal study. Am J Clin Nutr *98:389–395, 2013.*

*Cobalamin concentrations are shown in both pmol/L and (in parentheses) ng/L. Methylmalonic acid (MMA) data are shown in nmol/L.

Mild Dietary Insufficiency in Breastfed Infants. A series of Norwegian studies beginning in 2001 documented unexplained elevations of serum MMA levels in 60% of normal, asymptomatic 4- to 6-month-old Norwegian infants whose mothers were not cobalamin deficient.[205,206,212,254] The MMA elevation exceeded 1000 nmol/L in 30% of the infants,[254] and median serum MMA was 780 nmol/L in infants aged 6 weeks to 6 months, compared with 290 nmol/L in newborns and 130 nmol/L in children aged 1 to 10 years.[205] As Table 10-4 shows, plasma tHcy was also higher in the 6-week to 6-month age group, although not as strikingly abnormal as MMA.[205] Cobalamin levels tended to be low-normal or, in only 8% of cases, slightly subnormal.[254] These biochemical changes, which could also be easily reversed with cobalamin supplements,[206] usually normalized spontaneously after several months.[205] The absence of clinical signs of deficiency suggests that these normal infants had subclinical deficiency.

The explanation for the transient cobalamin status changes in early infancy has now become clearer. A recent longitudinal Danish study[108] documented an unexplained, apparently spontaneous decline in breastmilk cobalamin levels in healthy, omnivore mothers 4 months after giving birth, often despite their taking cobalamin supplements. The authors associated this decline in breastmilk cobalamin with the transiently worse cobalamin status in exclusively breastfed infants compared with infants eating mixed diets (Table 10-6). At month 9, the breastmilk cobalamin content had improved spontaneously, as had the cobalamin status of the infants (whose diet had also become mixed). The mothers' cobalamin status remained unchanged throughout these fluctuations of breastmilk cobalamin. It remains possible that additional factors play a role because breastfed infants who also ingest a mixed diet showed somewhat similar cobalamin findings as exclusively breastfed infants at 4 and 9 months.[108] The findings are compelling, but their surprisingly high frequency in seemingly normal mothers and infants requires clarification. More studies outside Scandinavia are needed as well. It is also important to note that this transient cobalamin deficiency of early infancy is subclinical. Convincing clinical accompaniments, including changes in hemoglobin and MCV levels, have not been reported. Finally, it is noteworthy that plasma folate levels remained unchanged throughout these transient cobalamin deficiencies but decreased sharply after the age of 1 year and continued to decline throughout childhood (see Table 10-4).[205] The relatively high folate content of human breastmilk provides breastfed babies significantly better folate status than nonbreastfed infants.[255,256]

Severe Nutritional Deficiency Caused by Significant Maternal Deficiency. At the other extreme of the spectrum of dietary cobalamin insufficiency in infants lies a clinically severe deficiency. It is dominated especially by neurologic, cognitive, and developmental manifestations, probably because the first 6 months of life are crucial for brain development.[257] The syndrome affects children who are exclusively breastfed by mothers who have longstanding compromised cobalamin status that probably also compromised maternofetal cobalamin transfer. To date, most of the mothers have had clinically minimal, usually latent pernicious anemia, significant dietary insufficiency, or tropical sprue.[16,258,259] The mothers' extremely low breastmilk cobalamin content, found to be only 0.05 to 0.09 μg/L in a representative study,[196] compared with the more normal 0.29 to 0.76 μg/L concentrations in the healthy mothers summarized in Table 10-6, then converted the infants' already precarious cobalamin state at birth into clinically severe deficiency by exclusively breastfeeding them.

The affected children display megaloblastic anemia, myeloneuropathy, and tongue atrophy, but their less specific but prominent failure to thrive, vomiting, developmental delay, motor and social retardation, hypotonia, seizures, poor growth and myelination of the brain, and, less often, tremor can obscure the true diagnosis.[16,189-192,196,257-264] Diagnostic delays can take months or even a year or more; a single-institution survey of 27 cases diagnosed between 2000 and 2008 reported a median age at diagnosis of 10.4 months.[192] Cobalamin therapy, which can be oral but should preferably include parenteral injections in the beginning, quickly reverses the anemia and improves neurologic function, but neurologic, mental, and developmental residua often persist.[191,262,263] It is illustrative of the differences in consequences of cobalamin depletion that the infants are often catastrophically ill whereas their mildly cobalamin-deficient mothers are usually asymptomatic, often with only mild biochemical abnormalities. Occasional mothers display megaloblastic changes and increased MCV, which are mild.

Initially reported in India,[16,189,196] where the children often also showed hyperpigmented skin changes, the severe deficiency has been increasingly documented around the world.[192,263,264] The syndrome is believed to be the most common cause of clinical cobalamin deficiency in infancy, but its frequency is unknown. Two limited studies of state-run newborn screening laboratories that used tandem mass spectrometry estimated frequencies of 0.88 and 3.02 per 100,000 births.[265,266] Whether additional factors influence who develops the syndrome is unclear. A report of the syndrome in only one of two exclusively breastfed monozygotic twins of a vegan mother whose breastmilk cobalamin was only 0.037 μg/L illustrates the unresolved questions.[261] Prospective studies are awaited to identify all the risk factors, determine if less dramatically clinical deficiencies are common, and establish criteria for prevention.

Nutritional Deficiencies Unrelated to Maternal Influence

Poor cobalamin intake can occur worldwide but its impact is greatest wherever societal vegetarianism is prominent. Less well appreciated is poor intake in generally impoverished regions.[255,256,267] Most regional surveys have documented increased rates of mild, biochemically defined cobalamin insufficiency. However, systematic data are sparse in young children, and the frequency of clinically overt consequences is unknown. Low cobalamin levels were especially frequent in exclusively breastfed infants in India and elsewhere,[255,256,268] resembling the observations in normal, breastfed infants in Scandinavia. Deficiency appears to be subclinical, perhaps because maternal cobalamin status is only mildly or moderately compromised.

Once established, deficiency may persist despite dietary liberalization. Young Indian adults retain MMA and tHcy abnormalities without anemia even years after emigrating to the United States and liberalizing their diets.[269] Clinical sequelae may occur in children in macrobiotic communities, with residual cognitive changes in adolescents even years after their diet was partially liberalized.[270] However, the broad inadequacies of macrobiotic diets make specific attribution to cobalamin deficiency difficult. The benefits of routine supplementation of vegetarians, especially children, need to be studied systematically. Folate and cobalamin supplementation of Indian infants did not protect them against diarrhea and respiratory infections[271]; indeed, folic acid use may have increased diarrheal risk.

Protein-restricted diets, such as phenylketonuric diets, can produce varying degrees of MMA and tHcy elevation at all ages but clinical signs of cobalamin deficiency are infrequent.[272-274] Isolated low cobalamin levels or isolated mild MMA and tHcy elevations were reported in 11% and 13%, respectively, of diet-restricted patients of all ages.[273] Another study of adults, in whom phenylketonuric restrictions often ease, found that 29% had cobalamin levels less than 271 ng/L but only 3% had levels less than 203 ng/L.[274] The plasma tHcy elevations in 29% of subjects may have been influenced by the frequently low vitamin B_6 levels. Borderline or mild macrocytosis was apparent in 68% of cases but was unexplained and appeared to be unrelated to MMA abnormality.[274]

Cobalamin deficiency can develop in children raised on goat's milk, which contains only 0.07 to 0.18 μg/L cobalamin, a small fraction of the contents of cow's milk, breastmilk, and even sheep's milk.[16] Folate deficiency is a more common consequence.

The possibility that inadequacies of cobalamin, folate, or both contribute to the anemia in premature infants or blunt its responsiveness to erythropoietin and iron therapy seems plausible. However, objective evidence of cobalamin deficiency remains marginal. The few available clinical trials,[275,276] although frequently cited, are hard to interpret because many uncontrollable variables confound the infants' laboratory data, management, and course; for example, even the control subjects in the studies received folic acid. Megaloblastic changes have not been observed.

Acquired Disorders of Cobalamin Absorption

Pernicious Anemia (Loss of Intrinsic Factor)

Acquired pernicious anemia, a relatively infrequent disease, is by far the most common cause of clinically overt cobalamin deficiency in adults.[16,244] It arises from chronic atrophic gastritis, a common inflammatory disorder with reduced or absent acid and pepsin secretion, only when such gastritis progresses to also stop secreting IF. Most often, the precursor atrophic gastritis for pernicious anemia is not the more common, so-called type B pangastritis arising from *Helicobacter pylori* infection[277] but the less common type A atrophic gastritis that spares the antrum and has frequent autoimmune features.[16,278-280] Autoantibodies against gastric antigens are frequent and chiefly directed against IF (50% to 70% frequency in pernicious anemia) or against the membrane H^+,K^+-ATP pump subunits of parietal cells (80% to 90% frequency). A strong association also exists with other autoimmune disorders, especially those involving endocrine glands embryologically associated with the stomach, such as the thyroid gland.[16,281]

The poorly understood progression from gastritis to pernicious anemia, which often displays a familial predisposition, is infrequent.[16,282] Several years or decades may pass before the pathognomonic IF loss and cobalamin malabsorption appear that define pernicious anemia. A few years later, more than 80% of the cobalamin stores become depleted, leading to megaloblastic anemia and neurologic dysfunction. Therefore pernicious anemia is typically diagnosed in people in their 60s or older. The disease predominates in women, and it is most common in northern Europeans but occurs worldwide. It is worth noting that the absence of IF prevents both absorption of ingested cobalamin and reabsorption and salvage of biliary cobalamin. Moreover, the achlorhydria of pernicious anemia may allow bacterial colonization of the upper gastrointestinal tract,[283] whose additional effects deserve elucidation. Although the IF loss is irreversible, the cobalamin deficiency, anemia, epithelial changes, and, if treatment is started in time, neurologic symptoms respond to cobalamin therapy.

Acquired Pernicious Anemia in Children. Only infrequently does acquired pernicious anemia affect children, in whom it is sometimes called “juvenile pernicious anemia.” Affected children are usually adolescents, but patients as young as 8 years old have been described.[16] Juvenile pernicious anemia differs from hereditary IF deficiency, in which gastritis is not usually evident but is indistinguishable from the adult form of acquired pernicious anemia, some of whose ancillary features are magnified. A family predisposition is more obvious than in adult pernicious anemia, and autoimmune features such as antibody to IF and coexisting endocrinopathies are more prominent. In these characteristics, juvenile pernicious anemia closely resembles the acquired pernicious anemia in blacks, who are disproportionately affected in their 20s, 30s, and 40s and in whom antibody to IF is nearly universal[284]; curiously, however, the usually very frequent antibody to parietal cells is less often present in these patients.[285]

All children with acquired pernicious anemia should be screened for coexisting endocrinopathies, especially immune thyroiditis, but also hypoparathyroidism and adrenal insufficiency, and for iron deficiency as well because achlorhydria reduces iron absorption. Whether the children also have the increased risk for gastric cancers seen in adults,[16,279,286] especially for carcinoid tumors, which complicate 7% of cases of adult pernicious anemia,[286] is unknown but seems likely. If true, endoscopy may become advisable when the children become older. It is not yet clear whether the four reported cases of acquired pernicious anemia in young adults with sickle cell disease[287,288] bespeak a true association. Nevertheless, it suggests considering coexisting pernicious anemia when blood cell counts decrease or MCV increases unexpectedly in patients with sickle cell disease. It also suggests the importance of screening cobalamin status before giving folic acid supplements.

An uncommon variant of acquired pernicious anemia can affect young adults and children with agammaglobulinemia or common variable immunodeficiency.[289] Bacterial overgrowth of the upper intestine is frequent, and the risk for gastric cancer is high.[289] Pernicious anemia can be hard to diagnose because agammaglobulinemic patients do not display diagnostic antibodies and the pangastritis characteristic of this syndrome prevents diagnostically helpful hypergastrinemia, which requires antral sparing.

The diagnosis of pernicious anemia has become difficult in general since the disappearance of the Schilling test of cobalamin absorption.[290] Testing for antibody to IF, which has greater than 90% specificity for pernicious anemia (as long as blood is not sampled within 1 to 2 days after cobalamin injection) is the best diagnostic tool left, and it is especially useful in juvenile pernicious anemia in which IF antibody is found much more frequently than the 50% to 70% sensitivity in adult pernicious anemia. Both parietal cell antibody, a marker of chronic immune gastritis, and serum gastrin elevation[279] have 80% to 85% sensitivity for pernicious anemia but lack specificity. Because of the low frequency of pernicious anemia, false abnormal results outnumber true abnormal results in both of those tests.

Other Acquired Gastric Disorders

Total gastrectomy eliminates IF secretion but is a rare procedure. Partial gastrectomy leads to eventual IF loss in 15% to 30% of adult patients, especially if chronic gastritis coexisted.[16,291] Preventive cobalamin treatment is advisable because megaloblastic anemia and neurologic abnormalities may develop after a few years. Most partial resections, as well as many current bariatric procedures, do not affect IF but induce a mild malabsorption limited to food-bound cobalamin that is usually associated with only subclinical, biochemical deficiency.[199,292-294] It is reasonable to institute preventive cobalamin supplementation and annual monitoring. Nonsurgical causes of food-bound cobalamin malabsorption, in which reduced acid and pepsin secretion and other poorly understood influences impair release of cobalamin from its binding proteins in food to IF, include chronic gastritis, which is much more common than pernicious anemia, and chronic use of acid-suppressing drugs, such as gastric proton-pump inhibitors.[199] Subclinical cobalamin deficiency often occurs, but clinical deficiency with signs and symptoms is unusual. These common forms of limited malabsorption in adults have not been studied in children.

Acquired Intestinal Malabsorption

Because cobalamin absorption is maximal in the terminal ileum, deficiency is likeliest in diseases that affect the ileum, such as tropical sprue. Sprue affects natives and visitors in endemic regions, but it can be latent, and diarrhea and vitamin deficiencies may not appear in visitors until much later. The megaloblastic anemia of sprue may arise from folate deficiency, cobalamin deficiency, or both; and the deficiencies and disease characteristics can vary not only among India, Southeast Asia, and the Caribbean but also locally[295]; neurologic consequences of cobalamin deficiency are unusual. The mechanism of tropical sprue is unknown, but a microbial component appears likely. The sprue often remits with tetracycline, especially in the Caribbean region where bacterial overgrowth has been observed[295]; sulfa drugs can be substituted in children, who may develop sprue less often than adults.[296] Folic acid itself sometimes augments the reversal. The frequency of tropical sprue has decreased since the 1980s, perhaps because of improved hygiene.

Ileal resection, such as after necrotizing enterocolitis[297] or Crohn disease, can cause cobalamin malabsorption. Clinically overt deficiency results if enough ileum is resected. Celiac disease and dermatitis herpetiformis primarily affect the upper small intestine, causing low cobalamin levels in only 11% to 12% of cases and rarely producing cobalamin-deficiency megaloblastic anemia.[298] More often, patients have folate and iron deficiencies, as discussed in the section on folate malabsorption.

Acquired Malabsorptive Disorders Originating in the Intestinal Lumen. Accumulation of bacteria in the small intestine accompanies some primary intestinal malabsorptive disorders, but its relevance is uncertain. Nevertheless, overgrowth of bacteria that utilize cobalamin can sometimes compete with IF for cobalamin and cause cobalamin deficiency.[299] One survey attributed 1% of cobalamin-deficiency megaloblastic anemias in adults to this intestinal disorder.[244] Causes of major overgrowth include blind loops, strictures, and abnormal intestinal motility.

Cobalamin-avid parasites, such as *Diphyllobothrium latum,* which parasitizes freshwater fish in northern countries, especially Finland, compete for ingested cobalamin in direct proportion to the gastrointestinal parasite load.[16] Severe cobalamin deficiency and megaloblastic anemia, which improve after worm expulsion, affect only 9% of carriers; neurologic abnormalities may also occur. Older adults are affected most often, but children as young as 9 years have been described.[16] The frequency of *D. latum* infestation has decreased greatly today, perhaps from pollution of northern freshwater lakes. The nature and relevance of the occasional association between *Giardia lamblia* and cobalamin malabsorption, especially in children and immunocompromised patients, and the low cobalamin levels seen in patients with heavy *Strongyloides stercoralis* infection are unclear.

The low intestinal pH seen in the Zollinger-Ellison syndrome interferes with IF uptake by ileal receptors, which requires a neutral pH.[300] Pancreatic insufficiency often causes abnormal results in the Schilling test of cobalamin absorption because pancreatic proteases must degrade haptocorrin to make cobalamin available to IF.[301] However, cobalamin deficiency has not been reported convincingly in adults. Cobalamin malabsorption also occurs in children with cystic fibrosis,[302] and cobalamin-responsive anemia was described in at least one such child 12 years after cystic fibrosis was diagnosed.[303]

The long list of drugs and toxins associated with cobalamin malabsorption includes colchicine, neomycin, paraaminosalicylic acid, and alcohol. The mechanisms are largely unknown. The absence of confirmed reports of clinical consequences is probably best explained by the several years of unremitting malabsorption needed to deplete stores in adults, whereas most drugs are taken too briefly or intermittently. The potential for drug effects in infants, with their limited cobalamin stores, is unknown. Metformin has been associated with low cobalamin levels, but the low levels are unexplained and are not associated with known cobalamin deficiency.[304,305]

Acquired Disorders of Cobalamin Metabolism

Nitrous Oxide Toxicity

On exposure to transition-metal complexes such as cobalamin, nitrous oxide can become an oxidizing agent, converting reduced cob(I)alamin to cob(III)alamin. One result is rapid, irreversible inactivation of methionine synthase for which cobalamin is a cofactor[306]; methylmalonyl-CoA mutase activity is less severely affected. In the usual intraoperative use of nitrous oxide lasting a few hours at most, a mild, transient metabolic abnormality occurs without clinical impact as the degraded enzyme is soon replaced.[307-309]

Clinical consequences arise only in special settings. One setting involves chronic, recurrent exposure: either as chronic occupational exposure to nitrous oxide[310] or as chronic inhalational abuse, which is especially popular among teenagers and young adults.[311,312] A quite different setting arises when a surgical patient who has unrecognized clinical cobalamin deficiency, such as pernicious anemia[313-315] or veganism,[316] receives nitrous oxide, especially when the anesthetic exposure is lengthy or repetitive. The consequences of nitrous oxide toxicity because of unrecognized clinical cobalamin deficiency appear within a few weeks of exposure; the timing of cumulative toxicity from repetitive nitrous oxide abuse is less clear and may depend on the extent and timing of exposure. The manifestations include megaloblastic anemia, but the neurologic and mental consequences are especially prominent. MMA and especially tHcy abnormalities are evident, but cobalamin levels are usually normal unless the patient had antecedent cobalamin deficiency, such as pernicious anemia. The diagnosis should be suspected if surgery was done recently, whereas chronic inhalational abuse may be denied. Response to cobalamin is often prompt, but neurologic residua can persist despite therapy.

Postoperative deterioration has been reported in two infants who received nitrous oxide and had severe neurologic dysfunction.[317,318] One child was exclusively breastfed and his mother was suspected to have pernicious anemia, a combination that may have contributed as much to his deterioration as his 80-minute exposure to nitrous oxide; he had severe megaloblastic anemia a mere 6 days after the surgery.[317] The role of nitrous oxide appeared more dominant in the other child, whose surgery took 3 hours and whose feeding and maternal history was less dramatic, although the mother had somewhat limited intake of animal products.[318] The child was not evaluated for hereditary or other contributors to cobalamin deficiency. A third report described a child with seizures and brain atrophy who died with respiratory distress 46 days after prolonged nitrous oxide exposure and was found to have severe MTHFR deficiency.[319] The mechanisms underlying the fatal outcome are not clear but raise concerns that nitrous oxide may worsen folate metabolism as well as cobalamin metabolism, especially in infancy. However, an attribution of neurologic deterioration after nitrous oxide exposure to common, mild MTHFR polymorphisms[320] was unconvincing because the single patient on which it was based also had a very low cobalamin level, probably caused by pernicious anemia, and the patient's effective treatment had included cobalamin.

Nitrous oxide should be avoided in any surgical or dental patient with suspected cobalamin deficiency, although the risk for adverse effects in the large number of healthy elderly persons and vegetarians with subclinical cobalamin deficiency is unknown. The value of routine preoperative screening of cobalamin status or routine preoperative supplementation requires analysis. Caution about using nitrous oxide seems prudent in children, especially infants with hereditary disorders of cobalamin and folate metabolism.[321] If nitrous oxide must be used, patients found to have cobalamin deficiency before surgery can be given cobalamin in advance, although the most effective timing and regimens await definition.

Increased Cobalamin Requirements

Increased requirements have been described in hyperthyroidism and some malignant diseases, but modern metabolic evidence is sparse. Given the large stores-to-daily intake ratio for cobalamin in adults and older children, clinical consequences are unlikely in the absence of contributing dysfunction, such as poor intake or malabsorption. Infants may be more susceptible to increased cobalamin requirements, but evidence is limited.

DIAGNOSTIC APPROACH TO ACQUIRED CAUSES OF COBALAMIN DEFICIENCY

Diagnosing Cobalamin Malabsorption

In adults, malabsorption accounts for more than 90% of cases of clinically expressed cobalamin deficiency.[244] Comparable data are not available in children, in whom malabsorption is less common. Moreover, the disappearance of reliable absorption testing with the Schilling test has left a major diagnostic gap.[290] A new test measuring the rise in plasma holo-TC after three oral doses of nonradioactive cyanocobalamin over 2 days[322] has been studied mostly in normal subjects, but validation in patients with proven malabsorption has been scarce. The current absence of reliable means to test cobalamin absorption leaves only indirect tests for some absorptive disorders. Anti-IF antibody is highly specific for pernicious anemia, but sensitivity is only 50% to 70%; sensitivity may be higher in juvenile pernicious anemia. Tests of gastritis, such as serum gastrin, lack specificity for pernicious anemia. A combination of IF antibody and gastrin testing may improve detection. No tests exist for intestinal causes of cobalamin malabsorption.

Diagnosing Dietary Cobalamin Deficiency

Dietary deficiency can be serious in infants, and diagnostic attention can focus on three major causative elements: maternal cobalamin deficiency, exclusive breastfeeding, and vegetarian diet (i.e., specific, rather than broad, dietary inadequacy). Maternal evaluation should be done routinely whenever any infant suffers from cobalamin deficiency or has elevated MMA, especially when cobalamin deficiency is severe or the infant was exclusively breastfed. The mother herself is usually asymptomatic, even when cobalamin deficient, so dietary history, serum cobalamin and MMA levels, and a blood cell count should be obtained. If maternal deficiency is suspected, IF antibody testing of the mother is warranted and the possibility of bowel disease should also be considered.

In older children, maternal influence is unlikely, but other contributory causes should be considered in the child before attributing any clinically expressed cobalamin deficiency to poor diet.

Diagnosing Acquired Metabolic Disorders

Disorders of cellular uptake or metabolism deserve consideration whenever serum cobalamin levels are normal in a child, especially an infant with megaloblastic anemia, failure to thrive, and developmental delay. MMA and tHcy levels should be measured in all cases. The most frequent acquired metabolic disorder is nitrous oxide toxicity, which can be suspected in children with recent anesthetic exposure and in adolescents who abuse inhalants; the latter often deny exposure. Hereditary disorders, although more common in young children, should be considered even in older children because clinical expression can be delayed or overlooked, especially when masked by multivitamin supplementation.

ACQUIRED CAUSES OF FOLATE DEFICIENCY

The underlying causes of acquired folate deficiency are listed in Box 10-2. Folate deficiency, formerly affecting more than 16% of adults and children of all ages, has nearly disappeared in countries that have mandated fortification with folic acid,[238,323] in large part because diet usually plays the major causative role in folate deficiency.

Dietary Folate Insufficiency

The stores–to–daily losses ratio for folate is relatively small at all ages, and poor intake for any reason can deplete stores quickly. Cooking and processing of food can also degrade folate content.[16] The wide distribution of folate in all food groups often means that folate deficiency can be accompanied by a relatively broad dietary inadequacy and that other nutrients may also be at risk. Alcoholism is a major contributor to folate deficiency in adults, often accompanied by a poor diet. However, alcohol and its breakdown products also directly affect folate absorption, transport, and catabolism.[324]

Infants, with their small folate stores and large demands for growth and development, are at risk if intake decreases. All these factors are magnified in premature

Box 10-2 Causes of Folate Deficiency in Adults and Children[*]

INADEQUATE NUTRITION[†]

- Poor diet[‡]
- Poor food preparation methods
- Exclusive feeding with goat's milk

DEFECTS IN ABSORPTION

- Gastric achlorhydria[§]
- Diseases of the upper small intestine
  - Tropical sprue
  - Celiac disease
  - Dermatitis herpetiformis
  - Inflammatory bowel disease
- Oral pancreatic replacement therapy[§]
- Hereditary folate malabsorption

INCREASED REQUIREMENTS OR LOSSES

- Pregnancy
- Lactation[§]
- Prematurity[§,‖]
- Chronic hemolytic anemia[§]
- Dialysis
- Hyperthyroidism[§]
- Lesch-Nyhan syndrome

DISORDERS OF TRANSPORT

- Cerebral folate deficiency (genetic or acquired)[¶]

DISORDERS OF CELLULAR METABOLISM

- Drugs inhibiting folate metabolism
  - Antifolates (methotrexate and others)
  - Pyrimethamine[§]; trimethoprim[§]
  - Sulfasalazine[§]
  - Valproic acid[§,#]
- Inherited defects
  - Methylenetetrahydrofolate reductase deficiency
  - Methionine synthase deficiency (cblE and cblG diseases)
  - Dihydrofolate reductase deficiency
  - MTHFD1 deficiency
  - Others

MULTIFACTORIAL OR UNCERTAIN MECHANISMS

- Alcohol abuse[‡]
- Anticonvulsants[§]
- Oral contraceptives (?)[§]

[*] Folate deficiency often has multifactorial causes. Many of these causes may be mild and incapable by themselves of producing deficiency or overt clinical expression, unless additional causes augment the deficiency or limit the compensation.

[†] Relative dietary insufficiency (i.e., intake that is adequate under usual circumstances) is a particularly important cofactor that can convert borderline folate deficiency to clinically overt deficiency when other conditions, such as increased requirements for folate or mild malabsorption, coexist.

[‡] Poor intake is often associated with alcoholism in adults.

[§] Megaloblastic anemia rarely results unless other limitations of folate status coexist.

[‖] Neonatal stores are low in premature infants.

[¶] Cerebral folate deficiency can occur on a genetic basis or an autoimmune basis; megaloblastic anemia does not occur because folate deficiency appears not to exist outside the central nervous system.

[#] Disrupts mitochondrial folate metabolism in utero.

newborns,[275] and megaloblastic anemia appearing at 6 to 11 weeks of life was described in 13% to 19% of premature infants.[16] Although breastmilk is relatively rich in folate (approximately 85 µg/L),[14] folate bioavailability from cow's milk is limited[16]; nonbreastfed infants often receive folic acid–fortified formulas and foods. Reliance on goat's milk poses another risk in infants.[16] The poor folate content of goat's milk (5 µg/L) may be a greater factor than the low cobalamin content in causing the megaloblastic anemia that appears at 18 to 20 weeks in infants dependent on goat's milk. Other dietary restrictions, such as the protein-restricted diet for phenylketonuria, occasionally induce folate deficiency. Finally, because folate deficiency (unlike cobalamin deficiency) is often part of a broader malnutrition, it is the usual cause of the megaloblastic anemia in disorders such as kwashiorkor and marasmus. Such children often require very high oral folic acid doses,[325] whereas cobalamin deficiency is rare. For unclear but probably largely dietary reasons combined with a growth spurt, folate status is somewhat lower (although usually normal) in adolescents than in younger children and remains so despite its dramatic improvement after fortification of the American diet.[323]

Acquired Disorders of Folate Absorption

Intestinal Disorders

Malabsorption accounted for only 2% of folate-deficient megaloblastic anemia in a clinical survey of adult patients in the prefortification era,[244] and it usually arises from diseases of the jejunum. Thus celiac disease and dermatitis herpetiformis cause folate deficiency much more often than cobalamin deficiency. Megaloblastic anemia is nevertheless relatively uncommon.[298] Inflammatory bowel disease, such as Crohn disease, affects ileum predominantly, and folate deficiency is infrequent in newly diagnosed children.[326]

Tropical sprue, discussed in the section on intestinal cobalamin malabsorption, can involve enough of the small intestine to disrupt both folate and cobalamin absorption, and folate deficiency is often an early feature.[295,296,327] In some regions of the world or at some stages of the disease, one deficiency predominates over the other. In florid cases, megaloblastic anemia is prominent. As mentioned previously, tropical sprue often responds to antibiotics, and folic acid not only improves megaloblastic anemia caused by folate deficiency but also sometimes reduces the severity of the sprue itself. Because cobalamin and folate deficiencies can coexist, testing for both deficiencies is advisable before instituting therapy.

It is unknown if fortification of the diet with folic acid, which can bypass the carrier-specific jejunal absorption of reduced, polyglutamated folates and is readily absorbed by nonspecific mechanisms in the ileum,[14,39] has lessened the clinical deficiency caused by malabsorptive diseases in general. These nonspecific, secondary absorption processes may also explain why oral folic acid given in high doses, such as 2 to 5 mg once or twice daily, can be effective in malabsorptive folate deficiencies.

Drug-Induced Disorders of Folate Absorption and Metabolism

Drug-induced malabsorption has been described with various medications, such as sulfasalazine and anticonvulsants, especially hydantoins.[16,328] The normally smaller stores–to–daily intake ratio makes folate theoretically easier to deplete than cobalamin by drug-induced mechanisms. Nevertheless, clinical consequences, such as megaloblastic anemia, have been infrequent. Hydantoins sometimes cause mild macrocytosis, but only potent antifolates, such as methotrexate, induce megaloblastic anemia. Valproic acid has been shown to inhibit fetal folate metabolism.[328] Oral contraceptives can lower serum folate levels, but the mechanism is unknown and no metabolic or clinical consequences are apparent.

An alkalinized gastrointestinal environment, whether caused by atrophic gastritis, drugs that reduce gastric acid secretion, or alkalinizing pancreatic replacement therapy for pancreatic insufficiency, reduces folate absorption but rarely induces clinical folate deficiency.[329-331]

Increased Folate Requirement

Requirements can rise in some situations[14,16] and may occasionally compromise folate status, especially when combined with marginal folate intake that limits dietary compensation. Pregnancy and lactation are common settings of increased folate demand.[332-334] High cell turnover rates in some diseases, most prominently chronic hemolytic anemias such as sickle cell disease and thalassemia,[14,335] provide another setting. Folic acid supplementation is therefore given to sickle cell patients routinely in clinical practice. However, megaloblastic changes have been unusual in most conditions of increased requirement, unless additional causes for folate deficiency coexist, such as poor diet.[332-335] A randomized clinical trial of folate supplementation reported equivocal clinical benefits in patients with sickle cell disease.[336] tHcy elevation is not unusual in patients with sickle cell diseases, but it appears to be unrelated to folate deficiency.[337] It appears prudent to screen folate-supplemented patients for pernicious anemia, which affects blacks disproportionately often at a young age, and has been found in at least four patients with sickle cell disease.[287,288] Psoriasis has been associated with possibly increased folate demand. Folate is lost during dialysis, and folate supplementation is usually provided routinely.[14]

DIAGNOSTIC APPROACH TO ACQUIRED CAUSES OF FOLATE DEFICIENCY

A careful history can usually identify absolute or relative insufficiency of dietary folate intake and can also identify the known conditions that increase folate requirements. Direct tests of folate absorption are not available, which makes independent search for individual malabsorptive disorders necessary. A contemporary clinical reassessment in the postfortification era is needed to determine which causes of folate deficiency persist and who remains at risk for folate deficiency.

TREATMENT OF ACQUIRED DEFICIENCIES

Reversal of Megaloblastic Anemia and Other Clinical Manifestations

The sequence of improvement after therapy is outlined in Table 10-7. The earliest clinical response in patients with megaloblastic anemia, whether caused by cobalamin or folate deficiency, can be gauged by the reticulocyte count, which begins to rise within 3 days and usually peaks by day 7. The intensity of the reticulocytosis varies inversely with the severity of the anemia. If pancytopenia existed, leukocyte and platelet counts also rise. Neutrophil hypersegmentation, however, persists for several weeks. Full normalization of all blood changes, including MCV elevation, is completed by 6 to 8 weeks. An incomplete hematologic response, detectable within a week by a poor reticulocyte response, requires assessment. Either the diagnosis was incorrect, including the possibility that the wrong vitamin was chosen, or coexisting disorders are present. Iron deficiency, for example, may not be recognized until the megaloblastic anemia is treated.[16,202] Neurologic and cognitive dysfunction arising from cobalamin deficiency begins to improve in the first week as well, but the speed and completeness of the response vary. Reversibility tends to vary inversely with the severity and duration of the original symptoms[16,173] and may be especially problematic in infants with developmental consequences.

TABLE 10-7 Sequence of Clinical and Hematologic Improvement with Effective Treatment of Cobalamin or Folate Deficiency

Time	Change*
Day 1	*Ineffective hematopoiesis reverses.* Serum iron and bilirubin levels fall. Serum unsaturated iron-binding capacity increases. Marrow iron stores decrease. *Patient may begin feeling better.* In cobalamin deficiency, serum folate decreases transiently.
Day 2	Increases begin in reticulocytes, WBC (if low), and platelets (if low). *Erythropoiesis becomes normoblastic.* Serum iron may become transiently low. Serum potassium decreases transiently (influx into new cells). *Tongue soreness (if present) begins to improve.*
Day 3	Serum lactate dehydrogenase level decreases. In folate deficiency, serum cobalamin level begins to increase.
Day 5	*Reticulocyte count begins to peak.* RBC count begins to increase, and MCV may begin to decrease. *WBC and platelet counts usually become normal.* RBC folate level increases. Any iron deficiency that may have coexisted can be identified reliably. *MMA and tHcy levels begin to improve.*
Week 2	*Tongue and gastrointestinal symptoms clear.* *Neurologic abnormalities improve.* *Neutrophil hypersegmentation reverses and giant metamyelocytes disappear from bone marrow.* MCV improves.
Weeks 6-8	*Blood cell count and RBC indices (e.g., MCV) become completely normal.*

Modified from Carmel R: Megaloblastic anemia. In Brain MC, McCulloch PB, editors: Current therapy in hematology/oncology 1983-1984. *Philadelphia, 1983, BC Decker.*

MCV, Mean corpuscular volume; *MMA,* methylmalonic acid; *RBC,* red blood cell; *tHcy,* total homocysteine; *WBC,* white blood cell.

*Changes that have special clinical relevance are shown in italics.

Box 10-3 **Management of Acquired Cobalamin Deficiency**

MANAGEMENT TASKS

1. Reverse the cobalamin deficiency.* A single injection ensures assimilation and can reverse deficiency but must be followed by further therapy to consolidate reversal (see below).
2. Identify and, if possible, treat the underlying causative condition.
3. Determine dose and route of cobalamin repletion and maintenance regimens. The details usually depend on the underlying cause and often on the patient's age.
4. Determine duration of therapy, which is usually dictated by the underlying disorder and its reversibility.
5. Monitor completeness of clinical and metabolic response to therapy to confirm that the diagnosis was correct and to identify coexisting, sometimes obscured pretreatment complications.
6. Determine the need for periodic follow-up if the underlying cause of cobalamin deficiency is irreversible.
7. Educate the patient and family about management goals, underlying causes, and prognosis.

*Clinically expressed cobalamin deficiency must always be treated. However, the need to treat subclinical, purely biochemical cobalamin deficiency is not established in many, if not most, cases. An exception may exist if the patient has an underlying cause (e.g., malabsorptive disease, such as pernicious anemia) that predicts the likelihood of progression to clinically expressed deficiency.

Patients with subclinical deficiency (i.e., isolated biochemical changes), who far outnumber patients with clinical deficiency, have no clinical signs and symptoms that can improve.[201,232] If clinical improvement occurs, the deficiency must be reclassified as having been clinical, and the likelihood of underlying malabsorption or other causes that persist or progress increases.

Management of Acquired Cobalamin Deficiencies

Management does not end with the identification and reversal of the cobalamin deficiency (Box 10-3). It is important to define why the deficiency occurred, which helps determine many of the management steps.[202]

The initial cobalamin dose is usually given parenterally to ensure its assimilation in case of undetected malabsorption and thus begin the reversal of the deficiency. Either cyanocobalamin or hydroxocobalamin can be used[16,107,202]; the therapeutic details of methylcobalamin have been studied less intensively. Adults and adolescents usually receive an intramuscular 1000 μg cobalamin dose, which ensures retention of approximately 150 μg when cyanocobalamin is used (retention varies inversely with the dose size); the rest is excreted immediately in the urine. Retention of hydroxocobalamin is greater, allowing less frequent doses,[104,338] but some hydroxocobalamin preparations induce antibody to transcobalamin, which inflates cobalamin levels without compromising cobalamin status.[338] For young children, whose stores (and thus the absolute deficit to be repleted) are much smaller, 100-μg or even 50-μg doses suffice and can mean a smaller intramuscular injection volume. The dose amount does not determine the rapidity and extent of response[16] but may affect its duration.

Despite its immediate effectiveness, a single dose never suffices in treating clinically expressed cobalamin deficiency, which reflects severe depletion and often arises from a serious, persistent underlying cause. Subsequent doses are needed to consolidate the response, replete the stores, and prevent relapse. The latter maintenance can be oral in many cases but requires more frequent, high doses in patients with malabsorption.[107] The dose, schedule, and route details depend on whether the underlying causative disorder involves malabsorption, whether the cause is reversible, and whether the immediate goal is repletion of stores (which may require 1 to 2 months of weekly injections or large daily oral doses) or later steady-state maintenance, which can be achieved with an injection of cyanocobalamin monthly or with hydroxocobalamin injection every 2 months[202]; it cannot be predicted whether some patients require more frequent maintenance).[202] The details also depend on the child's and family's acceptance of injections. Adults with pernicious anemia or other malabsorptive diseases can be maintained with daily oral doses of 1000 μg, but effective, age-appropriate doses in young children with malabsorption have not been systematically defined. Cobalamin is considered nontoxic, but the long-term effects of daily oral doses of 1000 μg are unknown, especially in children. Increased risk for some cancers, for example, has been reported in elderly persons chronically receiving high cobalamin and folic acid doses.[339]

Irreversibility of the underlying cause of cobalamin deficiency (e.g., pernicious anemia) or strong cultural strictures (e.g., veganism) require lifelong cobalamin therapy. The underlying causes themselves can also carry risks and complications and require independent management. For example, children with acquired pernicious anemia remain at lifelong risk for autoimmune endocrinopathies, gastric carcinoid tumors, and perhaps gastric cancer.

Clinical monitoring of the response to therapy, including occasional metabolic ascertainment, serves many purposes.[202] As discussed in the previous section, therapeutic improvement confirms whether the deficiency was correctly diagnosed and can also unmask coexisting conditions. Full correction of cobalamin deficiency can be detected by a normal tHcy or MMA level by the second or third week. Vitamin levels (e.g., cobalamin and holo-TC) can be misleading monitors of therapeutic response, as discussed previously.[202,211] Metabolic monitoring can also provide early evidence of impending relapse after remission has been achieved. Monitoring can be continued annually in older children and more often in infants and those with severe underlying disorders.

Education of the patient and parents about the underlying disorder, its nature, and its prognosis is crucial. Patients and families too often discontinue treatment, even in pernicious anemia, and suffer clinical relapse.[175] Children also often discontinue maintenance therapy once they become independent.

Management of Acquired Folate Deficiencies

Folate deficiency is now rare in countries with folic acid–fortified diets.[23,209,238] Therefore management of the few adults and older children who do become folate deficient merits special inquiry. Dietary deficiency is easily treated by daily oral 1-mg doses of folic acid in adults and older children. In infants, megaloblastic anemia responds to doses as small as 10 to 50 μg, and 50 μg daily can maintain remission.[16] Parenteral folic acid is rarely needed unless the patient cannot take oral medications. Patients with malabsorptive disorders often respond to oral therapy, although larger folic acid doses up to 5 mg are usually given, depending on the child's age and size; however, monitoring of the response is advisable. Treatment with a reduced folate form, such as folinic acid or methylTHF, does not provide documented advantages in acquired deficiency unless a metabolic defect is suspected. Coexisting cobalamin deficiency should always be excluded before treatment, especially when large folic acid doses are used.

As in cobalamin deficiency, clinical improvement occurs within a week in clinically folate-deficient patients (see Table 10-7), whereas patients with subclinical deficiency show only biochemical change. Stores usually become repleted within 1 to 3 months, and continuation of folic acid therapy beyond that period is needed only if the underlying cause of the deficiency is irreversible. Continued status can be monitored more effectively and reliably with tHcy than with measurements of serum or red cell folate levels, which increase regardless of effectiveness.

Management of Subclinical Folate Deficiency

Folate deficiency continues to be a problem in countries without folic acid fortification of the diet. Even in countries with fortification and widespread self-supplementation, some infants and adolescents have marginal folate status, often without clinical expression. The health impact of subclinical folate deficiency, including the potential for it in persons with *MTHFR* polymorphisms, has been associated with a wide variety of disorders in the maternofetal setting (e.g., NTDs and other malformations), in infancy, and in adults (e.g., cognitive dysfunction, thrombosis, and cancer risk). However, aside from NTDs, evidence of causality and benefit from intervention has often proved disappointing in randomized clinical trials, with thrombotic risk being the most notable example.[73]

Folate Toxicity

In countries with fortified diets, many normal adults exceed the recommended 1-mg intake ceiling,[14] and self-supplementation augments intake further. Although folic acid is generally regarded as safe, the risk for masking the megaloblastic anemia of untreated cobalamin deficiency has been a long-standing clinical concern whose facts remain incompletely understood,[161,162] high oral doses reduced the effectiveness of epileptic control in some patients,[340] animals given very high intravenous doses displayed nephrotoxicity, and a clinical trial of high oral doses in patients with diabetic nephropathy found increased renal and vascular complications.[341] Moreover, broader questions of unrecognized long-term risks of high folate status are beginning to be examined. Unreduced folic acid, which can act as an oxidizing agent, accumulates in plasma and cells, but its impact is unknown.[342,343] The seemingly binary relationship between folate intake and cancer is discussed in another section, but a few specific cancer risks have been reported.[339] An Indian clinical trial comparing preventive effects of cobalamin and folic acid supplementation on infection risks in young children found that diarrhea and some respiratory tract infections actually increased with folic acid supplementation.[271] Many of the reports of toxicity need confirmation, but so do many claims of preventive benefits. Caution and more firm data are needed to determine the preventive benefits and risks for exposing normal individuals, especially children, to chronically high intakes of vitamins.

GENETIC DISORDERS CAUSING MEGALOBLASTIC ANEMIA

In addition to dietary and acquired deficiencies of folate and cobalamin, several rare genetic disorders can cause megaloblastic anemia. These include disorders affecting uptake and metabolism of folate or cobalamin, as well as thiamine responsive megaloblastic anemia, orotic aciduria, and 3-phosphoglyceride dehydrogenase deficiency.

Inborn Errors of Folate Transport and Metabolism

Hereditary Folate Malabsorption

Hereditary folate malabsorption (MIM 229050) has been reported in approximately 30 patients.[344-346] It is characterized by megaloblastic anemia, diarrhea, mouth ulcers, failure to thrive, and usually progressive neurologic deterioration. Megaloblastic anemia and low serum folate levels appear in the first few months of life. Patients fail to absorb folates across both the intestinal epithelium and the choroid plexus, resulting in decreased folate levels in blood and CSF. The uptake of folate by cultured and uncultured cells is within reference ranges. Mutations in the *SLC46A1* gene on chromosome 17q11.2, which encodes PCFT, have been identified in a number of patients.[34,347,348]

Hematologic changes respond to parenteral therapy with folic acid at doses used to treat dietary folate deficiency, or to pharmacologic doses of oral folic acid (up to 60 mg daily).[349] However, folic acid has proven ineffective in raising CSF folate levels even when given parenterally, and all successful treatments of hereditary folate malabsorption have utilized folinic acid. Successful therapeutic regimens have typically utilized parenteral folinic acid, although some patients have been successfully treated using oral folinic acid.[346] Doses and schedules have varied. Monitoring of CSF folate levels is critical, with modification of dose to ensure that it is maintained within the normal range (typically >15 ng/mL). Prompt diagnosis and commencement of therapy is important because neurologic deficits, if untreated, may become irreversible.

Cerebral Folate Deficiency

A second disorder of folate uptake results in isolated decreased cerebral methylTHF uptake and levels (MIM136430), resulting in neurologic findings (developmental delay or regression, hypotonia, seizures, visual disturbances, and autistic features), but it does not cause megaloblastic anemia.[350] This syndrome can therefore be difficult to connect to folate because all expected systemic features of folate deficiency are lacking: besides the hematologic normality, plasma tHcy and serum and red cell folate levels are normal, and intestinal folate absorption is normal. The disorder is caused by decreased function of folate receptor-α at the choroid plexus, as a result of either antibodies against folate receptor-α[351] or mutations in the *FOLR1* gene on chromosome 11q13.4.[352,353] Treatment with folinic acid (0.5 to 1 mg/kg) relieves many symptoms, although seizures may remain resistant to treatment. Folic acid therapy should be avoided.

Severe Methylenetetrahydrofolate Reductase Deficiency

Severe MTHFR deficiency (see Fig. 10-2, reaction 8; MIM 236250) is the most common inborn error of folate metabolism, with more than 100 cases known. Most patients come to medical attention as infants, with developmental delay, breathing disorders, gait abnormalities, seizures, and microcephaly. Other patients have presented later in childhood or as adults, and some remain clinically unaffected.[354-357] Elevated tHcy levels and homocystinuria are always present, whereas the serum methionine level is in the low-normal range or decreased.[358] This contrasts to classic homocystinuria due to cystathionine β-synthase deficiency, which is characterized by higher homocysteine levels and elevated methionine. In contrast to other disorders affecting homocysteine remethylation, megaloblastic anemia is rarely present, reflecting the lack of trapping of folate as methylTHF. Because methylTHF is the major circulating form of folate, MTHFR deficiency may result in functionally low levels of folate in the brain. MTHFR deficiency is inherited as an autosomal recessive trait. More than 55 mutations in the *MTHFR* gene on chromosome 1p36.3 have been identified in patients with severe MTHFR deficiency.[359-363]

The diagnosis of severe MTHFR deficiency is established by measurement of enzyme activity in the liver, leukocytes, or cultured fibroblasts or lymphocytes. The disorder has been difficult to treat, with a poor prognosis once neurologic involvement is evident. The most successful treatment has been with oral administration of betaine, which is a substrate for the liver enzyme betaine:homocysteine methyltransferase and has the double advantage of raising methionine and decreasing homocysteine levels. Treatment is most effective when it is started at an early age before neurologic damage becomes established.[364,365]

Dihydrofolate Reductase Deficiency

Three families have been described with deficiency of dihydrofolate reductase (MIM 613839), the enzyme responsible for regenerating THF from dihydrofolate formed during the reaction catalyzed by thymidylate synthase (see Fig. 10-2, reaction 3).[366,367] Patients have been characterized by megaloblastic anemia (in some cases pancytopenia) and neurologic problems including seizures and, in severely affected individuals, cerebral and cerebellar white matter atrophy. There were decreased cerebral folate levels in the presence of normal serum folate but decreased red cell folate levels. Dihydrofolate reductase activity was decreased in cell extracts, and mutations in the *DHFR* gene on chromosome 5q14.1 were identified in all affected individuals. Treatment with folinic acid resulted in correction of hematologic abnormalities, although neurologic problems persisted.

Glutamate Formiminotransferase Deficiency

Glutamate formiminotransferase deficiency (MIM 229100) is caused by mutations in the *FTCD* gene on chromosome 21q22.3 that encodes the bifunctional enzyme containing glutamate formiminotransferase and formiminoTHF cyclodeaminase activities. These sequential reactions remove the formimino group from formiminoglutamate, formed during catabolism of histidine in the liver and kidney, to form formiminoTHF, which is converted to 5,10-methenylTHF (see Fig. 10-2, reactions 6 and 7).[368] Formiminoglutamate excretion, either constitutively or in response to a histidine load, is the one constant feature of the disorder. It is not clear whether this disorder, described in fewer than 20 patients, is associated with any consistent clinical findings. Two distinct phenotypes have been described: a severe form characterized by mental and physical retardation, abnormal electroencephalographic activity, and dilatation of the cerebral ventricles with cortical atrophy; and a mild form, with no mental retardation but higher levels of formiminoglutamate excretion.[358] Several patients had macrocytosis and hypersegmentation of neutrophils. Because the relationship between clinical expression and formiminoglutamate excretion is uncertain, the value in reducing formiminoglutamate excretion is unknown. *FTCD* mutations have been identified in two families with this disorder.[369]

MTHFD1 Deficiency

A single patient has been described with deficiency of the trifunctional enzyme encoded by the *MTHFD1* gene, which catalyzes synthesis of 10-formylTHF from THF and mitochondrially derived formate (formylTHF synthetase) and the conversion of 10-formylTHF to 5,10-methenylTHF (methenylTHF cyclohydrolase) and 5,10-methyleneTHF (methyleneTHF dehydrogenase; see Fig 10-2, reactions 9, 10, and 11).[370,371] The patient presented with megaloblastic anemia, atypical hemolytic uremic syndrome, and severe combined immune deficiency, which was partially responsive to therapy with hydroxocobalamin and folates. The patient has been shown to be heterozygous for two missense mutations in the *MTHFD1* gene.[370]

Inborn Errors of Cobalamin Transport and Metabolism

Inborn Errors of Cobalamin Absorption

Cobalamin absorption can be impaired by mutations affecting either IF production (hereditary IF deficiency; MIM 26100) or the ileal cubam receptor that recognizes the IF-cobalamin complex (Imerslund-Gräsbeck syndrome; MIM 261100). Symptoms typically appear after the first year of life but before age 5 years, reflecting time required for sufficiently extensive depletion of cobalamin stores, although onset as late as adolescence has been observed.[372] In addition to megaloblastic anemia there may be failure to thrive, weight loss, and recurrent gastrointestinal or respiratory tract infections.

Fewer than 100 cases of IF deficiency have been published, but the disorder is more frequent than this number suggests. Unlike in classic pernicious anemia, patients have no evidence of gastritis; gastric acid secretion is normal, there is no hypergastrinemia, antibodies against gastric parietal cells and against IF are absent, and increased risk for gastric cancer or carcinoids has not been reported. However, occasional patients show basal achlorhydria,[372] and reports have appeared of adult relatives who develop classic pernicious anemia with antibodies. There may be no detectable IF or production of an immunologically reactive but nonfunctional IF.[373-375] Mutations have been described in the *GIF* gene on chromosome 11q12.1 in several patients with this disorder,[376,377] including some patients who received a mistaken clinical diagnosis of Imerslund-Gräsbeck syndrome.

At least 300 cases of Imerslund-Gräsbeck syndrome (megaloblastic anemia 1), which is caused by deficiency in the ileal cubam receptor, have been described. This suggests that it is the most common hereditary cause of cobalamin deficiency. Many patients have proteinuria that is neither of the classic glomerular or tubular type and does not progress to kidney failure,[378] reflecting the role of cubam in reabsorption of filtered proteins, including albumin, in the kidney.[379] The disorder was initially recognized among Finns and Norwegians, but it is now more frequently diagnosed in patients from eastern Mediterranean countries. Imerslund-Gräsbeck syndrome may be caused by mutations affecting either the *CUBN* (chromosome 10p13) or *AMN* (chromosome 14q32.32) gene.[380-384] A mutation in the *CUBN* gene has been shown to cause isolated proteinuria in one family,[385] and a specific missense variant in the gene has been described as a risk factor for albuminuria and possibly for end-stage renal disease.[386,387]

With the disappearance of the Schilling test for malabsorption,[290] which can usually distinguish between loss of IF and failure of its uptake in the intestine, clinical differentiation between IF deficiency and Imerslund-Gräsbeck syndrome has become more problematic, leading to the suggestion that sequencing of the causative genes (*GIF, AMN,* and *CUBN*) represents the optimal first-line approach strategy for accurate diagnosis.[377] Treatment of both IF deficiency and Imerslund-Gräsbeck syndrome involves intramuscular injection of cobalamin, bypassing the block in intestinal cobalamin absorption. The goals are reversal of the deficiency, replenishment of body stores, and lifelong maintenance therapy. The details are similar to those discussed in the section on acquired malabsorptive disorders.

Transcobalamin Deficiency

More than 50 patients with transcobalamin deficiency (MIM 275350) are known. Because the direct compromise of cellular delivery bypasses cobalamin stores, patients develop severe anemia at a much earlier age than do patients with malabsorption, usually in the first months of life. Other symptoms include failure to thrive, weakness, and diarrhea. The anemia is clearly megaloblastic, but some patients present with pancytopenia or even isolated erythroid hypoplasia.[388] The presence of immature white cell precursors in a marrow that is otherwise hypocellular can lead to the misdiagnosis of leukemia.[389,390] For unknown reasons, neurologic disease is less prominent than in other cobalamin disorders but can appear from 6 months to 30 months after initial presentation,[391-394] in some cases because diagnostic delay led to therapeutic delay as well as sporadic treatment with folic acid.[395] Severe immunologic deficiency with defective cellular and humoral immunity has been reported, as has defective granulocyte function. Serum cobalamin levels are usually normal,[392] because most circulating cobalamin exists bound to haptocorrin, which is not affected, but occasional patients have low serum cobalamin levels.[392,396] Patients may have no detectable transcobalamin, or immunologically reactive transcobalamin that is unable to mediate vitamin delivery into cells.[397,398]

The diagnosis of deficiency requires measuring plasma transcobalamin levels by immunoassay or by transcobalamin-specific cobalamin-binding capacity assay; neither test is widely available. Transcobalamin is synthesized by cultured cells, including fibroblasts and amniocytes[399]; deficiency can be diagnosed by measurement of ability of cultured cells to take up labeled cobalamin in the absence of exogenous transcobalamin. Mutations in the *TCN2* gene on chromosome 22q12.2 have been identified.[400,401] Cobalamin treatment involves high-dose parenteral hydroxocobalamin (1000 mg); once cobalamin body stores have been replenished, injections at least once weekly are required to maintain health.[401] Monitoring of hematologic or biochemical parameters is necessary to ensure effectiveness of therapy. Therapy with cyanocobalamin instead of hydroxocobalamin and oral instead of intramuscular administration may be associated with poorer outcome.[401]

Haptocorrin (Transcobalamin I) Deficiency

Severe hereditary deficiency of haptocorrin (MIM 193090) is characterized by absent or near-absent haptocorrin in plasma, granulocytes, and all exocrine secretions.[402-404] Because haptocorrin, unlike transcobalamin, does not deliver its cobalamin to cells, cobalamin deficiency does not develop. However, because it carries more than 70% of cobalamin in plasma at any given moment, haptocorrin deficiency causes low serum cobalamin levels, often less than 100 ng/L in severe haptocorrin deficiency and only slightly low or low-normal in mild haptocorrin deficiency, in which haptocorrin levels are mildly low. Deficiency is typically identified in adulthood, when a patient might undergo cobalamin testing for unrelated reasons and typically receives an initial misdiagnosis as cobalamin deficiency and unnecessary treatment.

Only nine cases of severe haptocorrin deficiency have been published, which represents underreporting of an easily overlooked, symptom-free condition. A prospective survey reported absent haptocorrin in 3 of 537 (0.6%) sera with low cobalamin levels.[223] The latter study also found mild haptocorrin deficiency in another 15% of such blood samples, compared with 2.8% to 5.4% of various control groups. All nine known patients with severe deficiency to date have been nonwhite, and all who were genotyped were homozygotes or compound heterozygotes for nonsense or missense *TCN1* mutations, most often the nonsense mutation 270delG. Heterozygosity for this or other mutations has been found in more than half of unrelated persons with mild haptocorrin deficiency and in all mildly affected relatives of propositi with severe deficiency, but not in unaffected relatives.[288,405,406]

Several patients with haptocorrin deficiency have also had neurologic problems that appear to be unrelated to the low cobalamin levels or the haptocorrin deficiency[402-404,407]; for example, cobalamin therapy did not prevent progression of neurologic disease in the equally severely haptocorrin-deficient sibling of the original propositus.[402,403,407] A child with hereditary deficiencies of both IF and haptocorrin (both encoded by genes on the long arm of chromosome 11) has been described.[408] The original family with severe haptocorrin deficiency[402] was later shown to have combined haptocorrin and lactoferrin deficiencies[407]; these two proteins are coexpressed in neutrophil specific granules and secretions, but the family had the *TCN1* 270delG mutation, leaving the coexisting lactoferrin deficiency unexplained. Finally, it is noteworthy that globin mutations, especially hemoglobin S and C, coexist disproportionately often with haptocorrin deficiency in blacks, but the mutational dosages do not always match.[288]

Mild haptocorrin deficiency may be responsible for many unexplained low cobalamin levels without clinical or subclinical deficiency.[223] However, it is more difficult to diagnose than severe deficiency in which haptocorrin is absent. The diagnosis should not be made without objective evidence, using haptocorrin measurement or genetic testing, as happened in one poorly documented case,[409] where improvement of neuropathy and mild macrocytosis after cobalamin treatment was also overlooked.

Acquired haptocorrin deficiencies appear to be limited to plasma and can accompany severe neutropenic conditions.[407] Other proposed associations of acquired haptocorrin deficiencies include human immunodeficiency virus disease, multiple myeloma, and metformin use and require further study.

Inborn Errors of Cellular Cobalamin Metabolism

Several inborn errors of cobalamin metabolism, designated cblA to cblG, cblJ, and cblX, have been identified, each representing mutations at a different gene.[153,410-414] These disorders result in isolated hyperhomocysteinemia and homocystinuria, isolated methylmalonic acidemia and aciduria, or combined homocystinuria and methylmalonic aciduria, depending on whether synthesis of MeCbl, AdoCbl, or both cobalamin cofactors is affected. Only those disorders in which synthesis of MeCbl is impaired, either alone (cblE, cblG, cblD variant 1) or in combination with AdoCbl synthesis (cblC, cblD, cblF, cblJ, cblX), are characterized by megaloblastic anemia. Disorders in which synthesis of AdoCbl alone is impaired (cblA, cblB, cblD variant 2) are not associated with megaloblastic anemia. Traditionally, these disorders have been differentiated on the basis of studies of cultured fibroblasts.[415,416] With the identification of the genes underlying each of these disorders, specific diagnosis can now be achieved by mutation analysis of potentially causative genes in patient genomic DNA. All of these disorders are inherited as autosomal recessive traits, with the exception of cblX, which is X-linked.

Functional Methionine Synthase Deficiency. Functional methionine synthase deficiency is characterized by elevated tHcy, homocystinuria, and hypomethioninemia without methylmalonic aciduria. On the basis of complementation analysis, three distinct groups of patients have been identified: cblE (MIM 236270); cblG (MIM 250940); and cblD variant 1 (MIM 277410). The clinical and biochemical findings in these disorders are virtually identical. Patients usually present in the first 2 years of life, but some have not been symptomatic until adulthood. Patients typically present with megaloblastic anemia; neutropenia, thrombocytopenia, and pancytopenia have been reported. Other findings have included developmental delay, cerebral atrophy, electroencephalographic abnormalities, nystagmus, hypotonia, hypertonia, ataxia, seizures, microcephaly, and blindness.[417] Renal problems, including atypical hemolytic uremic syndrome and an atypical glomerulopathy, have been described in cblE patients.[418,419] Findings in patients with adult onset of symptoms have typically involved neurologic or psychiatric symptoms. One patient with onset at 21 years of age was diagnosed as having multiple sclerosis.[420]

Fibroblasts from all three groups of patients show decreased synthesis of MeCbl and decreased methionine synthase function in the presence of normal AdoCbl synthesis and methylmalonyl-CoA mutase activity.[417,421] Methionine synthase specific activity in cell extracts is decreased in cblG, which is caused by mutations in the *MTR* gene that encodes methionine synthase.[422,423] In the cblE disorder, methionine synthase specific activity is normal when the assay is performed in the presence of adequate reducing agent, but unlike in cblG, activity is decreased when the assay is performed using suboptimal levels of reducing agent.[417] The cblE disorder is caused by mutations in the *MTRR* gene, which encodes methionine synthase reductase; this protein maintains the enzyme-bound cobalamin cofactor in its active reduced form.[424] The cblD disorder is discussed in the next section on combined deficiency of AdoCbl and MeCbl.

Generally, systemic therapy with OHCbl, at first daily and then once or twice weekly, has been used to treat these disorders. Treatment with betaine, which increases homocysteine remethylation by the liver enzyme betaine homocysteine methyltransferase, has also been recommended.[365] Treatment corrects the anemia and metabolic abnormalities. The neurologic findings have been difficult to reverse, particularly in cblG disease; this stresses the importance of early diagnosis and therapy. A mother carrying a fetus identified by prenatal diagnosis as having the cblE disorder was treated from the second trimester with systemic OHCbl.[425] The infant was treated from birth and has done very well. It is uncertain how much prenatal therapy contributed to this favorable outcome.

Combined Deficiency of Adenosylcobalamin and Methylcobalamin. The cblC, cblD, cblF, cblJ, and cblX disorders are characterized by decreased synthesis of both MeCbl and AdoCbl, with resultant deficient activity of both methionine synthase and methylmalonyl-CoA mutase. Affected individuals present with combined homocystinuria and methylmalonic aciduria. These disorders affect early steps in cobalamin metabolism subsequent to hydrolysis of the holo-TC complex in lysosomes. In the cblF and cblJ disorders, transfer of free cobalamin from lysosomes to the cytoplasm is affected (see Fig. 10-5). The cblC, cblD, and cblX disorders affect metabolism of cobalamin after it enters the cytoplasm and before it becomes associated with either methionine synthase in the cytoplasm or methylmalonyl-CoA in the mitochondria.

The cblC Disorder. The cblC disorder (MIM 277400) is the most common of the inborn errors of cobalamin metabolism, with more than 550 patients identified. Patients have homocystinuria and methylmalonic aciduria, with hypomethioninemia and cystathioninuria. Presentation is usually in the first year of life, with lethargy, poor feeding, failure to thrive, and developmental delay.[426-428,429] Most patients have megaloblastic anemia, and some have hypersegmented neutrophils and thrombocytopenia. Others have onset later in childhood[430,431] or in adulthood,[432-434] with spasticity, myelopathy, delirium, dementia, or psychosis. Some patients have had onset of problems prior to birth.[428,435] A characteristic pigmentary retinopathy with perimacular degeneration has been observed in several patients,[431,436-438] and a number of patients have had an atypical hemolytic uremic syndrome.[429,439] A high frequency of structural heart defects has been reported.[440]

Fibroblasts show decreased synthesis of both MeCbl and AdoCbl and decreased function of both methionine synthase and methylmalonyl-CoA mutase. Endocytosis of the transcobalamin-cobalamin complex and release of cobalamin from lysosomes into the cytoplasm occur normally,[441] but total intracellular cobalamin levels are markedly decreased in most cases, reflecting inability of cells to retain cobalamin that is not bound to intracellular proteins. The cblC disorder is caused by mutations in the *MMACHC* gene on chromosome 1p34.1.[442] The MMACHC gene product binds cobalamin after its release from the lysosome and appears to play a role in removal of its upper axial ligand, generating a partially reduced form that can be converted to MeCbl or AdoCbl.[154-156]

Therapy can be difficult, particularly in patients with early onset. In one series, about one third of patients with onset in the first month of life died.[426] Parenteral OHCbl therapy, 1 mg/day, has been shown to reduce MMA and homocystine excretion. OHCbl rather than CNCbl should be used, and parenteral OHCbl treatment is much more effective than oral therapy.[443,444] In some cases, frequency of dosage has been reduced as the patient's condition stabilizes, although this may be associated with suboptimal outcome.[428] One study found that extremely high doses of OHCbl (up to 20 mg/day) were necessary to maintain biochemical control.[445] Betaine (250 mg/kg/day) appears to be helpful when used in combination with OHCbl. Neither folinic acid nor carnitine has any effect.[443] Therapy with daily oral betaine and biweekly injections of OHCbl reduced MMA levels, normalized serum methionine and tHcy concentrations, and resolved lethargy, irritability, and failure to thrive. However, complete reversal of the neurologic and retinal findings did not occur; this emphasizes the need for early diagnosis and treatment. Even with good metabolic control, surviving patients usually have moderate to severe developmental delay.[426,429] The prognosis appears to be better in patients with a later age at onset.

The cblD Disorder. The cblD disorder (MIM 277410) was initially described in a patient who presented at age 14 years with a history of mild mental retardation, severe behavioral pathology, and a poorly defined neuromuscular problem, with no hematologic findings. His younger brother, clinically asymptomatic, was shown to have the same disorder[446,447]; interestingly, deoxyuridine suppression testing demonstrated cobalamin deficiency in bone marrow cells despite their normal morphologic appearance.[447] Both boys had methylmalonic aciduria and homocystinuria.[446] Fibroblasts showed a biochemical phenotype indistinguishable from that of cblC fibroblasts, but their disorder could be differentiated from cblC by complementation analysis.[411] Subsequently identified cblD patients have presented with isolated homocystinuria in the absence of methylmalonic aciduria (cblD variant 1), whereas others presented with methylmalonic aciduria in the absence of homocystinuria (cblD variant 2). All cases of this disorder are caused by mutations in the *MMADHC* gene on chromosome 2q23.2.[448] The product of the *MMADHC* gene interacts with the MMACHC protein and appears to be involved in determining whether cobalamin becomes associated with methionine synthase in the cytoplasm or with methylmalonyl-CoA mutase in the mitochondria. Mutations affecting its carboxy terminal region were associated with isolated homocystinuria, and mutations affecting the amino-terminal region were associated with isolated methylmalonic aciduria, whereas truncating mutations were associated with combined homocystinuria and methylmalonic aciduria.

The cblX Disorder. Approximately a dozen patients have been described with decreased synthesis of both AdoCbl and MeCbl as a result of mutations affecting the *HCFC1* gene on chromosome Xq28.[414] These patients had received a diagnosis of cblC disorder on the basis of complementation analysis, but no *MMACHC* mutations could be identified. Clinically they have been characterized by a particularly severe neurologic disorder, while at the cellular level cobalamin coenzyme synthesis appears less severely affected than in the cblC disorder. The *HCFC1* gene encodes a transcriptional coregulator that in conjunction with a second factor, THAP11, is required for expression of several genes, including *MMACHC*.

Expression of MMACHC is markedly decreased in fibroblasts from cblX patients.

The cblF and cblJ Disorders. Fifteen patients with the cblF disorder (MIM 277380) and three with the cblJ disorder (MIM 614857) have been described. Clinical presentation has been variable, with no findings shared by all the patients who have been studied. Frequent findings include being small for gestational age, poor feeding, failure to thrive, growth retardation, and persistent stomatitis. Macrocytic anemia, neutropenia, thrombocytopenia, and pancytopenia have been observed. Two patients had minor facial abnormalities, and at least three have had cardiovascular defects.[152,449-453] Typically, there is hyperhomocysteinemia and methylmalonic aciduria, although elevated tHcy could not be detected in the blood of the first patient with cblF disorder who was described. Cobalamin absorption and serum cobalamin levels have been decreased in several patients.[454-456]

Fibroblasts from patients with cblF and cblJ disorders show decreased function of both cobalamin-dependent enzymes and decreased synthesis of both MeCbl and AdoCbl. Unlike cblC and cblD fibroblasts, there is accumulation of large amounts of intracellular cobalamin, with almost all of it being unmetabolized free CNCbl present within lysosomes.[153,449,457,458] The defects in both disorders appear to impair transport of cobalamin that has been released from transcobalamin across the lysosomal membrane into the cytoplasm. The gene affected in the cblF disorder is *LMBRD1* on chromosome 6q13, which encodes a lysosomal membrane protein of unknown function.[152] The cblJ disorder is caused by mutations in the *ABCD4* gene on chromosome 14q24.3, which encodes a lysosomal membrane ATP-binding cassette transporter.[153] Abnormal intestinal absorption of cobalamin has been documented in two patients with cblF disorder, suggesting that the same lysosomal transport system plays a role in transport of cobalamin across ileal cells.[454,455]

The patients with these disorders appear to respond to systemic therapy with OHCbl, although the first patient responded to oral cobalamin. A concern is that patients may accumulate cobalamin in lysosomes to such an extent that it impairs other lysosomal functions, although there is no evidence to date that this has occurred.

Thiamine-Responsive Megaloblastic Anemia

The thiamine-responsive megaloblastic anemia syndrome (TRMA; MIM 249270) is a rare autosomal recessive disorder characterized by the triad of megaloblastic anemia, diabetes mellitus, and sensorineural deafness that responds to pharmacologic doses of thiamine.[459-463] The bone marrow is characterized by megaloblastic changes and ringed sideroblasts. In some cases, pancytopenia has been reported.[464,465] Additional clinical findings have included visual impairment (optic atrophy, retinal dystrophy, Leber congenital amaurosis), cardiomyopathy, neurologic problems (strokelike episodes, seizures), and short stature.[462,466] More than 70 affected individuals have been reported. Presentation is typically within the first 5 years of life. Megaloblastic anemia and diabetes have responded to therapy with oral thiamine hydrochloride, although in some cases thiamine therapy became ineffective at puberty and patients required ongoing insulin therapy and blood transfusion.[462,467] Hearing loss appears to be irreversible even with thiamine treatment.[468]

Thiamine (vitamin B_1), essential for cellular metabolism, is synthesized by bacteria, fungi, and plants. Humans must acquire the vitamin in their diets. Uptake of thiamine by cells is mediated by two high-affinity thiamine transporters: thiamine transporter 1, encoded by the *SLC19A2* gene on chromosome 1q24.2; and thiamine transporter 2, encoded by the *SLC19A3* gene on chromosome 2q36.3. Once taken up by cells, thiamine is converted to its active coenzyme derivative, thiamine pyrophosphate, by the enzyme thiamine pyrophosphokinase (EC 2.7.6.2). Thiamine pyrophosphate is required for the activity of four known mammalian enzymes: transketolase (EC2.2.1.1), a component of the nonoxidative pentose phosphate pathway; pyruvate dehydrogenase (EC1.2.4.1), which converts pyruvate to acetyl-CoA; oxoglutarate dehydrogenase (EC1.2.4.2), which converts α-ketoglutarate to succinyl-CoA; and branched-chain α-ketoacid dehydrogenase (EC1.2.4.4), which is involved in catabolism of branched-chain amino acids. Impaired activity of transketolase has been suggested to underlie megaloblastosis in thiamine-responsive megaloblastic anemia.[469]

All cases of TRMA that have been investigated are caused by mutations affecting the *SLC19A2* gene.[462,463,470-472] Fibroblasts from patients with TRMA have decreased thiamine uptake relative to control fibroblasts and, unlike control cells, undergo apoptosis when incubated in medium lacking thiamine.[473] More than 30 mutations in the *SLC19A2* gene have been reported in patients with TRMA.[462,463] The tissue specificity of the clinical findings in TRMA may be the result of patterns of expression of the two thiamine transporter proteins, with tissues that do not express thiamine transporter 2 *(SLC19A3)* being affected.

Hereditary Orotic Aciduria

Fifteen well-established cases of hereditary orotic aciduria (MIM 258900) have been described over the past 40 years.[474-476] Patients are characterized by a macrocytic hypochromic megaloblastic anemia that does not respond to therapy with either folate or cobalamin and by orotic acid crystalluria. Additional findings observed in some patients have included some degree of physical and intellectual delay, urinary tract obstruction (due to orotic acid crystals), cardiac malformations, strabismus, and immune problems. Biochemical studies have demonstrated decreased function of uridine monophosphate synthase, a bifunctional enzyme that contains the two terminal enzymes involved in de novo synthesis of uridine monophosphate: orotate : pyrophosporyl transferase (EC2.4.2.10) catalyzes conversion of orotic acid to orotidine monophosphate; and orotidine monophosphate decarboxylase (EC4.1.1.23), which catalyzes conversion of orotidine monophosphate to uridine monophosphate. Analysis of the *UMPS* gene on chromosome 3q21.2 in two patients with hereditary orotic aciduria demonstrated the presence of causative mutations.[477]

Patients have generally responded well to treatment with oral uridine (50 to 300 mg/kg/day) with resolution of megaloblastic anemia and reduction of orotic acid excretion, although a single patient required intramuscular uridine.[478] Requirement for uridine supplementation is lifelong.

3-Phosphoglyceride Dehydrogenase Deficiency

Megaloblastic anemia has been reported in some, but not all, patients with 3-phosphoglycerate dehydrogenase (EC 1.1.1.95) deficiency (MIM 601815),[479,480] a rare disorder that results in impaired ability to synthesize serine from 3-phosphoglycerate. Although serine is a nonessential amino acid, impairment of this pathway results in severely decreased levels of serine in the serum and CSF,[480] demonstrating that the diet alone does not provide sufficient serine to support normal metabolism. Patients with this disorder are characterized by microcephaly beginning prior to birth, with severe psychomotor delay and intractable seizures developing during the first year of life. Cataracts, hypogonadism, adduction of the thumbs, and thrombocytopenia were present in some patients.

The disorder is characterized biochemically by markedly decreased levels of serine in CSF and by decreased plasma serine after an overnight fast. The low levels of serine in the CSF may reflect relatively low affinity of the neutral amino acid transporter for serine, leaving the central nervous system particularly dependent on de novo serine synthesis to meet its metabolic needs.[480] The level of methylTHF in CSF is also reduced.[479] Because under normal conditions serine represents the major source of one-carbon units for cellular folate metabolism, serine deficiency may thus result in decreased levels of folate coenzyme forms required for nucleotide synthesis. Patients have been treated with high doses of serine, and in some cases with glycine as well. Treatment has resulted in correction of biochemical deficits and decreased frequency of seizures, but no progress in psychomotor development has been observed in patients when treatment was started after 1 year of age.[481] One affected individual who was identified by prenatal diagnosis and who was treated with serine beginning in the prenatal period has shown normal development.[482]

Mutations in the *PHGDH* gene on chromosome 1q12 have been identified in several patients with 3-phosphoglyderate dehydrogenase deficiency.[483,484] Seven different mutations have been identified, including six missense and one deletion that results in a frameshift. All mutations resulted in enzymes with very low residual activity in vitro.[483,484]

A review of the relative strengths and shortcomings of current biochemical tests of cobalamin status in clinical and subclinical cobalamin deficiencies.

233. Clarke R, Sherliker P, Hin H, et al: Detection of vitamin B_{12} deficiency in older people by measuring vitamin B_{12} or the active fraction of vitamin B_{12}, holotranscobalamin. *Clin Chem* 53:963–970, 2007.

The study reports modest diagnostic superiority for holotranscobalamin over cobalamin testing for methylmalonic acid abnormalities but concludes that poor positive predictive values make both tests unreliable for screening asymptomatic persons for cobalamin deficiency.

245. Vogiatzoglou A, Oulhaj A, Smith AD, et al: Determinants of plasma methylmalonic acid in a large population: implications for assessment of vitamin B_{12} status. *Clin Chem* 55:2198–2206, 2009.

Methylmalonic acid is often considered the best available test of cobalamin status, but this study shows that the four known influences on it (only one of which is cobalamin status) explain less than 17% of the test's variation.

247. Refsum H, Smith AD, Ueland PM, et al: Facts and recommendations about total homocysteine determinations: an expert opinion. *Clin Chem* 50:3–32, 2004.

The consensus of a panel of acknowledged experts on homocysteine testing.

254. Hay G, Clausen T, Whitelaw A, et al: Maternal folate and cobalamin status predicts vitamin status in newborns and 6-month-old infants. *J Nutr* 140:557–564, 2010.

The prospective study of 364 mother-infant pairs shows that maternal status predicts the infants' folate and cobalamin status not only at birth but also after 6 months.

264. Honzik T, Adamovicova M, Smolka V, et al: Clinical presentation and metabolic consequences in 40 breastfed infants with nutritional vitamin B_{12} deficiency—what have we learned? *Eur J Paediatr Neurol* 14:488–495, 2010.

This analysis of 40 breastfed infants with often severe cobalamin deficiency provides a useful perspective on this important entity that urgently needs systematic, prospective information.

288. Carmel R, Bellevue R, Kelman Z: Low cobalamin levels associated with sickle cell disease: contrasting origins and clinical meanings in two instructive patients. *Am J Hematol* 85:436–439, 2010.

Two patients with sickle cell hemoglobinopathy and low cobalamin levels, one caused by pernicious anemia and the other by haptocorrin deficiency, provide new lessons about potential associations and diagnostic challenges.

305. Greibe E, Trolle B, Bor MV, et al: Metformin lowers serum cobalamin without changing other markers of cobalamin status: a study on women with polycystic ovary syndrome. *Nutrients* 5:2475–2482, 2013.

A correction of an all too frequent tendency to equate low serum cobalamin levels with cobalamin deficiency, which had popularized unsupported claims that the serum cobalamin decline after metformin use reflects cobalamin deficiency.

312. Ng J, Frith R: Nanging. *Lancet* 360:384, 2002.

This case report of severe neurotoxicity from recurrent abuse of nitrous oxide also describes a popular mode of inhalational abuse in young people.

323. Pfeiffer CM, Caudill SP, Gunter EW, et al: Biochemical indicators of B vitamin status in the US population after folic acid fortification: results from the National Health and Nutrition Examination Survey 1999-2000. *Am J Clin Nutr* 82:442–450, 2005.

Evidence that fortification of the diet with folic acid has greatly reduced the frequency of folate deficiency at all ages, including young children, in the United States.

339. Ebbing M, Bonaa KH, Nygard O, et al: Cancer incidence and mortality after treatment with folic acid and vitamin B_{12}. *JAMA* 302:2119–2126, 2009.

Chronic supplementation with folic acid and cobalamin increased risk for cancer, especially lung cancer, in Norway; possible explanations why other studies have not found similar risks include the lack of distortion of control data by fortification and the study's focus on folic acid, rather than food folate, intake.

346. Geller J, Kronn D, Jayabose S, et al: Hereditary folate malabsorption: family report and review of the literature. *Medicine* 81:51–68, 2002.

Description of a patient and a review of clinical findings in hereditary folate malabsorption.

354. Thomas MA, Rosenblatt DS: Severe methylenetetrahydrofolate reductase deficiency. In Ueland PM, Rozen R, editors: *MTHFR polymorphisms and disease*, Georgetown, TX, 2005, Landes Bioscience, pp 41–53.

A review of the clinical presentation in methylenetetrahydrofolate reductase deficiency, the most common inborn error of folate metabolism.

371. Keller M, Ganesh J, Heltzer M, et al: Severe combined immunodeficiency resulting from mutations in *MTHFD1*. *Pediatrics* 131:e629–e634, 2013.

Description of a patient with megaloblastic anemia, severe combined immune deficiency, and atypical hemolytic uremic syndrome due to a novel inborn error of folate metabolism.

377. Tanner SM, Li Z, Perko JD, et al: Hereditary juvenile cobalamin deficiency caused by mutations in the intrinsic factor gene. *Proc Natl Acad Sci U S A* 102:4130–4133, 2005.

Mutation analysis in patients with intrinsic factor deficiency and state-of-the-art approach to identifying inborn errors affecting cobalamin absorption.

401. Trakadis YJ, Alfares A, Bodamer OA, et al: Update on transcobalamin deficiency: clinical presentation, treatment and outcome. *J Inher Metab Dis* 2013. [Epub ahead of print].

Review of clinical and molecular genetic findings in a series of patients with transcobalamin deficiency.

428. Carrillo-Carrasco N, Chandler RJ, Venditti CP: Combined methylmalonic acidemia and homocystinuria, cblC type: I. Clinical presentation, diagnosis and management. *J Inher Metab Dis* 35:91–102, 2012.

429. Carrillo-Carrasco N, Venditti CP: Combined methylmalonic acidemia and homocystinuria, cblC type: II. Complications, pathophysiology, and outcomes. *J Inher Metab Dis* 35:103–114, 2012.

Two articles presenting a thorough review of what is known about the cblC disorder.

442. Lerner-Ellis JP, Tirone JC, Pawelek PD, et al: Identification of the gene responsible for methylmalonic aciduria and homocystinuria, cblC type. *Nat Genet* 38:93–100, 2006.

Identification of the causal gene for the cblC disorder, the most common inborn error of cobalamin metabolism.

448. Coelho D, Suormala T, Stucki M, et al: Gene identification for the cblD defect of vitamin B_{12} metabolism. *N Engl J Med* 358:1454–1464, 2008.

Identification of the causal gene for the cblD inborn error of cobalamin metabolism and proposal of a hypothesis to explain its multiple clinical and biochemical presentations.

470. Labay V, Raz T, Baron D, et al: Mutations in *SLC19A2* cause thiamine-responsive megaloblastic anemia associated with diabetes mellitus and deafness. *Nat Genet* 22:300–304, 1999.

Identification of the causal gene in thiamine-responsive megaloblastic anemia.

Iron lacks the glitter of gold and the sparkle of silver but outshines both in biologic importance. This plebeian metal is vital to the function of a wide variety of critical enzymes, including catalases, aconitases, ribonucleotide reductase, peroxidases, and cytochromes, which exploit the flexible redox chemistry of iron to execute a number of chemical reactions essential for our survival (Box 11-1). In addition, we depend on hemoglobin, another iron-containing protein, to transport inhaled oxygen from the lungs to peripheral tissues. Human existence is inextricably linked to iron, and disturbances in its metabolism may have dire consequences.

PHYSIOLOGIC CHEMISTRY OF IRON

Iron and Oxidation

The key to the biologic utility of iron is its ability to exist in either of two stable oxidation states: Fe^{2+} (ferrous) or Fe^{3+} (ferric). This property permits iron to act as a redox catalyst by reversibly donating or accepting electrons. An excellent example is the electron transport chain of oxidative phosphorylation, in which adenosine triphosphate (ATP) is generated from glucose by the orderly transfer of electrons through a network of iron-containing mitochondrial cytochromes.

When dissolved in aqueous solution, ferrous iron rapidly oxidizes to ferric iron, which is insoluble at physiologic pH. The resulting ferric hydroxide salts (rust) are of no metabolic utility. To achieve stable solubility under physiologic conditions, iron complexes with iron-binding agents termed chelators. Chelators are synthesized by all organisms, ranging from microbes (e.g., deferoxamine produced by *Streptomyces pilosus*) to humans (e.g., transferrin in human plasma). These molecules are important to environmental iron acquisition and transport as well as intracellular storage.

Iron-Protein Complexes

Iron-protein complexes capitalize on the properties of the metal to perform metabolic functions, the iron acting as the chemical workhorse and the protein dictating biologic specificity. Individual iron atoms can interact directly with amino acid side groups in proteins, as in ribonucleotide reductase. Alternatively, iron may form coordination

complexes with other small molecules. For example, protoporphyrin IX donates four of the six electrons needed to form a stable coordination complex with iron. Heme, the iron–protoporphyrin IX complex, is so stable that removal of the iron moiety requires an enzyme, heme oxygenase. The functional properties of heme are determined by the nature of the associated protein or small molecule ligands supplying the remaining two electrons. The best-characterized heme protein is hemoglobin, in which a globin histidine residue donates the fifth electron and the sixth comes from molecular oxygen.[1] This configuration enables hemoglobin to transport oxygen safely throughout the body.

Iron and sulfur atoms can also form complexes (clusters) that catalyze enzymatic reactions. The Krebs cycle enzyme aconitase, for example, contains an iron-sulfur (Fe/S) cluster. As discussed later in this chapter, the iron content of the Fe/S cluster of a related aconitase-like molecule allows it to “sense” iron concentrations within the cell and to act as an iron regulatory protein (IRP) to modulate the translation of genes of iron metabolism.

Iron Toxicity

The ability of iron to catalyze redox reactions also accounts for its toxicity. As an enzymatic cofactor, the metal is involved in the restructuring of cellular components. Unchelated iron has unbridled redox activity, however, and may contribute to cellular degeneration. We live in an oxygen-rich atmosphere, and our bodies require oxygen for many metabolic processes. However, oxygen is highly reactive and its interaction with iron potentiates its toxicity. Normal cellular reactions, including respiration, generate the reactive oxygen intermediates superoxide (O_2^-) and hydrogen peroxide (H_2O_2). Oxidative stress develops when production of reactive oxygen species exceeds the body’s processing capacity. Under these circumstances, reactive oxygen intermediates may be converted to injurious free radicals by the iron-catalyzed Fenton reaction[2]: Hydroxyl radicals promote the peroxidation of proteins, DNA, and membrane lipids, problems that are exacerbated by iron overload. Certain organelles are particularly susceptible to iron-dependent peroxidation. In iron-overloaded cells, injured mitochondria and lysosomes become leaky.[3] Mitochondrial damage and release of lysosomal proteases cause further cell injury and may ultimately lead to cell death. This process contributes to the severe tissue damage seen in the liver, heart, and endocrine organs of patients with iron overload disorders (see later).

Iron is not normally present in cell membranes. However, in both sickle cell disease and thalassemia, iron, heme, ferritin, and denatured hemoglobin adhere to the inner surface of the red cell plasma membrane and thereby contribute to the pathogenesis of these congenital anemias.[4,5] The membrane complex containing denatured hemoglobin has been termed *hemichrome*.[4,5] The red cell anion transport protein band 3 appears to nucleate the formation of these iron aggregates.[6,7] Injured cells decorated with membrane iron deposits are removed by a functioning spleen in patients with thalassemia and sickle cell–hemoglobin C disease (hemoglobin SC disease), but they circulate in functionally asplenic patients with homozygous sickle cell–hemoglobin S disease (hemoglobin SS disease). Membrane-associated iron promotes free radical formation and further membrane damage, marked by generation of the lipid peroxidation product malonyldialdehyde and by cross-linking of membrane proteins.[5,8] Membranes become rigid and thus contribute to the formation of irreversibly sickled cells that occlude the microcirculation.

Sometimes reactive oxygen intermediates can be beneficial. Neutrophils contain a membrane-associated reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase that produces superoxide to kill ingested microorganisms (reviewed by Clark[9]). Superoxide and secondary reactive oxygen intermediates are potent antimicrobial agents. Congenital defects in this NADPH oxidase, collectively termed *chronic granulomatous disease* (see Chapter 22), are characterized by a serious defect in defense against bacterial pathogens.

Neutrophils and iron also injure tissues in inflammatory diseases such as rheumatoid arthritis.[10] Synovial macrophages ingest red cell hemoglobin introduced by intermittent joint hemorrhage. Iron is deposited in the synovial membrane, proximate to superoxide and hydrogen peroxide generated by neutrophils and macrophages participating in the inflammatory reaction. Iron catalyzes the conversion of these compounds to free radical species, which promote lipid peroxidation. Iron therapy exacerbates this process. In contrast, antioxidants and iron chelators retard free radical generation, thereby affording some theoretic protection against injury in rheumatoid arthritis.[11,12]

These deleterious properties of iron are threatening only when the element is in a “free” state or in an abnormal form within the cell. Protection of cell structures from iron-dependent free radical damage is therefore of utmost importance. When iron is bound to protein either directly or indirectly, the generation of free radicals is largely abrogated. Thus, tight chelation of iron is a means of controlling its reactivity. As discussed later, cytoplasmic ferritin allows iron to be stored safely within cells by sequestering it in an innocuous form. Expression of ferritin is induced by oxidative stress.[13] Both prokaryotic and eukaryotic cells contain ferritins, and mice lacking one of the two ferritin genes do not develop past the early embryonic stages.[14] Thus, ferritin appears to be necessary for most, if not all, living cells.

ACQUISITION AND DISTRIBUTION OF IRON

The average adult has 4 to 5 g of iron. To maintain systemic iron homeostasis, a meticulous balance exists between dietary uptake and loss. Approximately 0.5 to 1 mg of iron is lost each day through sloughing of cells from skin and mucosal surfaces (Fig. 11-1).[15] Because menstruating females lose an average of an additional 1 mg of iron daily, their dietary iron requirement is increased.[16] Neither the liver nor the kidney has a significant physiologic capability to excrete iron. Consequently, absorption is the primary means of regulating body iron stores.[17] During neonatal and childhood growth spurts, iron requirements increase in response to augmentation of body, and particularly red blood cell, mass.

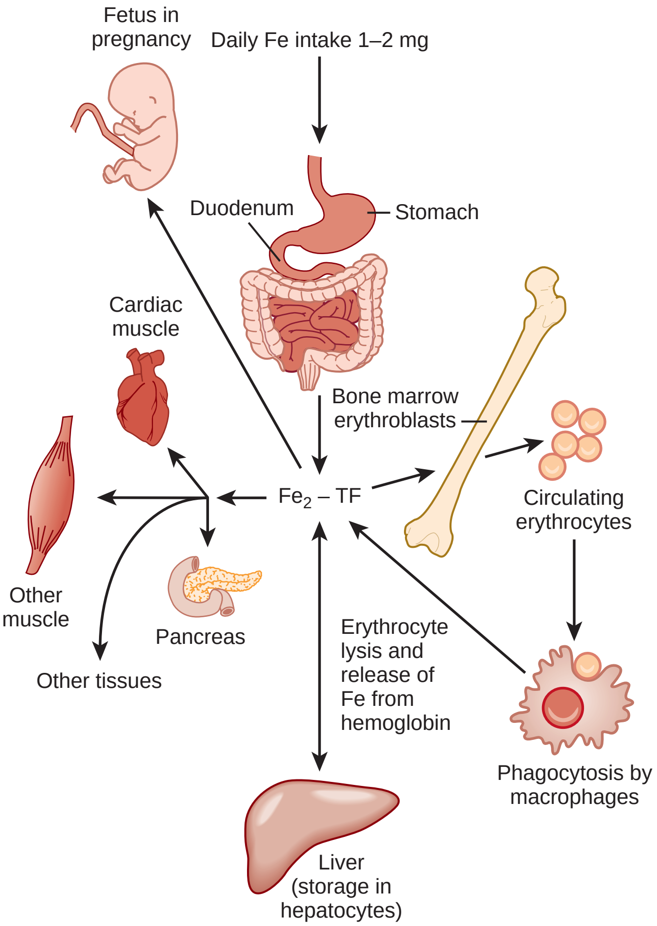

Figure 11-1 The body's iron economy. Although the average adult has 4 to 5 g of body iron, only 1 mg of dietary iron enters and leaves the iron economy on an average day. Dietary iron enters through the duodenum and becomes bound to plasma transferrin for delivery to tissues. The erythron is the largest site of iron use, but all cells require the metal. Storage iron is found primarily in the liver. Reticuloendothelial macrophages carry out iron recycling. Iron is lost from the body with bleeding and with exfoliation of skin and mucosal cells. *(Modified from Andrews NC: Iron homeostasis: insights from genetics and animal models.* Nat Rev Genet *1:208–217, 2000.)*

Iron Absorption

Iron absorption occurs predominantly in the proximal duodenum.[18,19] The physical state of iron entering the duodenum greatly influences its absorption. At neutral pH, ferrous iron is rapidly converted to the insoluble ferric form. Acid produced by the stomach serves to lower the pH in the duodenum and thereby enhance the solubility and uptake of iron (see later). Heme is absorbed separately from and more efficiently than inorganic iron,[18] independent of duodenal pH. Consequently, meat is an excellent nutritive source of iron. Heme iron absorption is, however, very poorly understood, but a heme oxygenase inhibitor has been shown to block heme catabolism in the intestine and result in an iron-deficient state.[20]

A number of dietary factors influence inorganic iron absorption.[21] Ascorbate and citrate increase iron uptake, in part by acting as weak chelators to help solubilize the metal in the duodenum. Iron is readily transferred from these compounds to the absorptive epithelium. Conversely, plant phytates, bran, and tannins inhibit iron absorption.[21-23] These compounds chelate iron and prevent its uptake by the absorption machinery.

Through a combination of genetic and biochemical approaches, much has been learned about the absorption of nonheme iron over the past two decades. Nonheme iron arrives at the apical surface of the absorptive duodenal enterocyte in its ferric (Fe^{3+}) form. It is reduced through the action of a brush border ferric reductase. This enzyme may be duodenal cytochrome *b*, a heme protein that is homologous to *b*561 cytochromes.[24] Expression of duodenal cytochrome *b* is significantly greater in the proximal duodenum than elsewhere and increases in iron deficiency.

Ferrous (Fe^{2+}) iron is then taken up by the enterocyte through the action of divalent metal transporter 1 (DMT1, also known as Nramp2, DCT1, and SLC11A2).[25,26,27] Transport requires the coordinated movement of protons in the same direction (symport). Thus, DMT1 functions only at low pH, and it has little or no activity at neutral pH. DMT1 is widely expressed, but duodenal levels increase dramatically in iron deficiency.[27,28]

DMT1 can also transport other divalent metal ions, including Cd^{2+}, Co^{2+}, Cu^{2+}, Mn^{2+}, Pb^{2+}, and Zn^{2+}.[27] Competition studies have shown that lead, manganese, cobalt, and zinc can share the intestinal absorption pathway used by iron. Increased iron absorption induced by iron deficiency also enhances the uptake of these elements. Because iron deficiency often coexists with lead intoxication, this interaction has vast public health significance and can produce particularly serious medical complications in children.[29] As discussed later, copper absorption and metabolism are handled by an entirely different mechanism.

After iron enters the absorptive enterocyte through the action of DMT1, it has at least two possible fates. It can be retained by the cell and subsequently be lost when the enterocyte dies and is sloughed into the intestinal lumen, or it can be transported across the basolateral membrane to enter the body. Iron retained by the enterocyte is used for cellular metabolism or incorporated into ferritin. Exported iron leaves the cell by way of a unique basolateral transmembrane iron transporter, ferroportin (FPN1, also known as SLC40A1, MTP1, and IREG1).[30,31,32,33]

Basolateral iron transfer also requires a change in the oxidation state of the metal, likely facilitated by the homologous multicopper ferroxidases hephaestin,[34,35] and ceruloplasmin, which are membrane associated and present in the plasma, respectively. A comprehensive model of intestinal iron absorption, primarily derived from studies in mice, is shown in Figure 11-2. This model pertains only to nonheme iron transport; details of heme iron uptake have not yet been worked out. A candidate intestinal heme transporter was reported but subsequently proven to be a folate transporter, instead.[36]

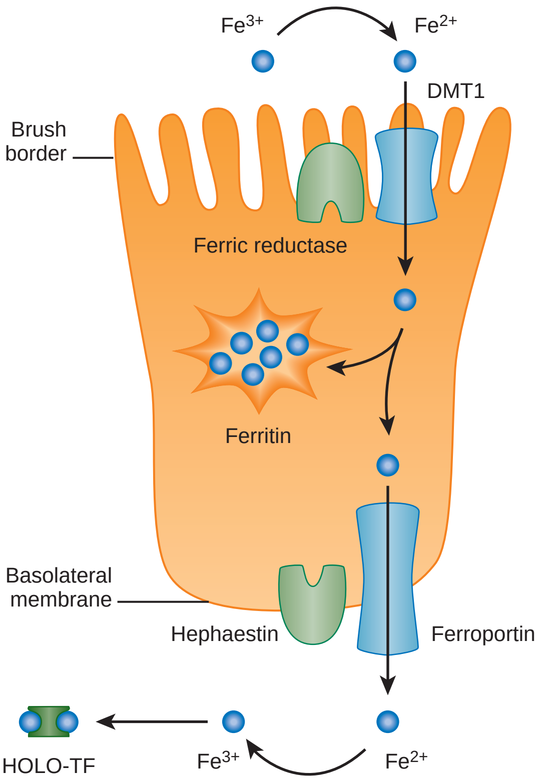

Figure 11-2 Duodenal iron transfer. The microstructure of the iron absorption apparatus is depicted in this cartoon. Iron is taken up by enterocytes lining the duodenal villi. These absorptive cells start out as undifferentiated precursors in the intestinal crypts. Crypt cells appear to be programmed for an iron absorption "set point" that is determined in response to iron needs. As the cells differentiate, they migrate up the villi and begin to express iron transporter proteins. According to current models, nonheme iron uptake occurs in mature enterocytes through the enzymatic reduction of iron, transmembrane import into the cell by DMT1, transmembrane export from the cell by ferroportin, and enzymatic oxidation by hephaestin before loading onto apotransferrin to produce diferric transferrin (HOLO-TF). *(Modified from Andrews NC: Iron homeostasis: insights from genetics and animal models.* Nat Rev Genet *1:208–217, 2000.)*

Normally, only about 10% of dietary nonheme iron entering the duodenum is absorbed. However, this value increases significantly with iron deficiency.[37] In contrast, iron overload reduces, but does not completely eliminate, absorption. Finch designated this modulation the "stores regulator."[37] In addition, both iron deficiency anemia and forms of anemia associated with ineffective erythropoiesis induce a marked increase in iron absorption. This effect has been designated the "erythroid regulator."[37] The erythroid regulator appears to exert a dominant effect over the stores regulator, as individuals with chronic persistent ineffective erythropoiesis can become profoundly iron overloaded even in the absence of transfusion. Hypoxia also increases iron absorption, independent of anemia.[38,39]

Hepcidin, an iron-regulated peptide hormone, links the actions of all these regulators through a unifying molecular mechanism. Hepcidin is a 25–amino acid peptide produced in the liver from a larger precursor (reviewed by Nemeth and Ganz[40]). It circulates in the plasma and binds to the iron exporter ferroportin on the basolateral surface of absorptive enterocytes, causing ferroportin to be internalized and degraded in a ubiquitin-dependent manner.[41] In this way, hepcidin controls cellular iron egress. Hepcidin thus regulates iron absorption at the level of the intestinal epithelium in that any iron unable to leave the enterocytes is lost when these cells turn over.

Expression of hepcidin is induced in response to iron overload[42,43] and inflammation[44,45] and is repressed in response to increased erythropoietic activity[45,46] and hypoxia.[45] Regulation of hepcidin levels appears to be at the level of gene transcription. However, the signals that govern hepcidin transcription in response to these stimuli are incompletely understood. Only the inflammatory cytokine interleukin-6 has been definitely shown to be involved in regulation of hepcidin expression by physiologic changes outside the liver.[47-49]

Most of the total body iron is ultimately incorporated into hemoglobin in erythroid precursors. An average adult produces 200 billion red cells daily to achieve a red cell renewal rate of 0.8% per day. Each red cell contains more than 1 billion atoms of iron, and each milliliter of packed red blood cells contains approximately 1 mg of iron. To meet this daily need for 2×10^{20} atoms (or 20 mg) of elemental iron, iron is recycled from senescent red cells and returned to the circulation. Plasma iron turnover (PIT) represents the mass turnover of transferrin-bound iron in the circulation (expressed as milligrams per kilogram per day).[50] Accelerated erythropoiesis increases PIT and enhances iron uptake from the gastrointestinal tract.[51] Although hepcidin appears to be the effector molecule that alters intestinal absorption, an upstream, circulating factor—the erythroid regulator—that communicates the iron needs of the erythron must exist.[41,52] There are some data to indicate that circulating bone morphogenetic protein (BMP) signaling pathway inhibitors (e.g., GDF15 and TWSG) may play a role in mediating this effect.[53,54]

This erythroid control of hepcidin expression is particularly apparent in patients with thalassemia intermedia (non–transfusion-dependent thalassemia), in whom marked iron overload develops even without transfusions. The accelerated, but ineffective, erythropoiesis substantially boosts iron absorption by inhibiting hepcidin expression.[55-58] By contrast, hepcidin is increased in patients with thalassemia and other anemias receiving chronic transfusion therapy as a consequence of iron overload and the suppression of erythropoiesis.[59]

Intercellular Iron Transport

Only a small proportion of total body iron enters and leaves the body each day. Consequently, intercellular iron transport is quantitatively more important than intestinal absorption. The greatest mass of iron is found in erythroid cells, which make up about 60% to 80% of the total body endowment in normal individuals. To accommodate ongoing erythropoietic needs, the reticuloendothelial system recycles approximately 20 to 25 mg of iron from effete red cells each day.

A small fraction, 0.1% or 4 mg, of total body iron circulates in plasma in an exchangeable pool. In normal individuals, nearly all of the circulating plasma iron is bound to transferrin. Transferrin serves three purposes: (1) it renders iron soluble under physiologic conditions; (2) it prevents iron-mediated free radical toxicity; and (3) it facilitates transport into cells. Transferrin is by far the most important physiologic supplier of iron to red cells.[60] In fact, plasma transferrin serves to deliver iron to most tissues of the body. It is an 80-kd glycoprotein that has homologous N-terminal and C-terminal iron-binding domains.[61] The molecule is related to several other proteins, including ovotransferrin in bird and reptile eggs,[62] lactoferrin in extracellular secretions and neutrophil granules,[63,64] and melanotransferrin (p97), a protein produced by melanoma cells.[65] The functions of these related proteins are incompletely understood. The human transferrin messenger RNA (mRNA) is 2.3 kilobases (kb) in length and encodes 679 amino acids, including a 19–amino acid leader sequence. It is located on chromosome 3q, near genes for the transferrin receptor and melanotransferrin. The liver is the major site of synthesis and secretion of transferrin.[66] Other tissues, including Sertoli cells of the testis, oligodendrocytes of the central nervous system, lymphocytes, muscle cells, and mammary cells, can, however, also produce the protein.[67-72] Local synthesis within the brain and testis apparently provides transferrin for these tissues because serum transferrin does not penetrate their unique capillary barriers.

Transferrin production is regulated at multiple levels. Several *cis*-acting control regions exist upstream of the gene. The transferrin promoter contains binding sites for tissue-specific nuclear factors that activate transcription differentially in the liver and other tissues (e.g., Sertoli cells).[73] Iron, hormones, and inflammatory stimuli also modulate transferrin gene expression.[74-78] In the setting of iron deficiency, serum transferrin levels rise substantially as a result of enhanced synthesis of transferrin mRNA by the liver.[76] In contrast, inflammation depresses levels of both serum transferrin and serum iron, the latter through the action of the iron regulatory hormone hepcidin. The plasma concentration of diferric transferrin has been proposed to modulate expression of the iron regulatory hormone hepcidin.[79] Liver-derived serum transferrin levels fall modestly in patients with genetic or acquired iron overload, although mRNA levels have been reported to be unchanged.[80] This suggests that hepatic transferrin is also controlled at the level of translation or secretion. The quantity of transferrin mRNA in nonhepatic tissues (including the testis, kidney, and spleen) is not affected by iron deficiency. The liver-derived transferrin, therefore, appears to have the unique responsibility of responding to iron status.

X-ray crystal structures have been determined for transferrin and related proteins (reviewed elsewhere[81,82]). All members of the transferrin protein superfamily exhibit similar polypeptide folding. The N-terminal and C-terminal domains are globular moieties of about 330 amino acids; each of these domains is divided into two subdomains, with the iron- and anion-binding sites located in the intersubdomain cleft on either side of a central plane of symmetry, suggesting an origin by gene duplication from a primordial protein containing a single iron-binding site. The binding cleft opens with iron release and closes with iron binding.[83] The N-terminal and C-terminal binding sites are very similar. No cooperativity exists in binding of iron by the two sites, and the protein can be proteolytically cleaved into two halves, each of which retains iron-binding capability.[84,85] Transferrin binds ferric iron much more avidly than ferrous iron.[86]

The precise mechanism by which iron is loaded onto transferrin as it leaves intestinal epithelial cells or reticuloendothelial cells is unknown. The copper-dependent ferroxidase ceruloplasmin and its homologue hephaestin likely play central roles in reducing ferrous iron exported by ferroportin 1 (FPN1) from the reticuloendothelial cells and intestine, respectively, although neither is absolutely required due to the tendency of iron to oxidize in aqueous environments.[87-89] Transferrin binds ferric iron exceptionally avidly, with a dissociation constant (K_d) of approximately 10 to 22 mol/L in the company of an anion (usually carbonate), which serves as a bridging ligand between the metal and protein and excludes water from two coordination sites.[86,90,91] Without the anion cofactor, iron binding is negligible; with it, ferric transferrin is resistant to all but the most potent chelators. Release of iron from transferrin involves protonation of the carbonate anion to loosen the metal-protein association.

The sum of all iron-binding sites on transferrin constitutes the total iron-binding capacity (TIBC) of plasma. Thus, on a molar basis, TIBC is twice the concentration of transferrin protein because each transferrin molecule can bind two iron atoms. The laboratory method used to measure the TIBC can either be truly the total iron-binding concentration of the plasma measured by iron binding or a calculation based upon measurement of the concentration of transferrin. Whatever the method, under normal circumstances, about a third of transferrin iron-binding sites are filled. Consequently, except for the situation of extreme iron overload, in which all transferrin-binding sites are occupied, non–transferrin-bound iron (NTBI) in the circulation is present at very low concentrations.[92] The distribution of plasma and tissue iron can be traced with the use of ^{59}Fe as a radioactive tag by reinfusing a subject with autologous transferrin loaded with radiolabeled iron. Blood samples can be analyzed at timed intervals to determine the rate of loss of the radioactive label. Such ferrokinetic studies indicate that the normal half-life of iron in the circulation is about 75 minutes.[50] The absolute amount of iron released from transferrin per unit time is the PIT (see earlier).

Such radioactive tracer studies indicate that at least 80% of the iron bound to circulating transferrin is delivered to the bone marrow and incorporated into reticulocytes.[93,94] Other major sites of iron delivery include the liver and the spleen, which are the primary depots for iron storage. Hepatic iron is found in both the reticuloendothelial cells and hepatocytes. Reticuloendothelial cells acquire iron primarily by phagocytosis and breakdown of effete red blood cells; they catabolize heme and return iron to the circulation, where it binds transferrin. Hepatocytes take up iron by at least two different mechanisms, which are transferrin-dependent and transferrin-independent. The relative amounts of iron in each of these cell types depend on clinical circumstances, as discussed in detail later.

Given the preeminent role of bone marrow in the clearance of labeled iron from the circulation, ferrokinetic studies provide a window on erythropoietic activity. Conditions that augment erythrocyte production increase PIT. For example, hemolytic anemias such as hereditary spherocytosis and sickle cell disease induce rapid delivery of transferrin-bound iron to the marrow. In contrast, disorders that reduce red cell production, such as Diamond-Blackfan anemia and aplastic anemia, prolong PIT.

When erythrocytes are produced and released into the circulation in a normal fashion, the process of erythropoiesis is termed *effective*. In patients with certain anemias, however, the abnormal, nascent red cells apoptose or are destroyed before they leave the marrow cavity. In this situation, erythropoiesis is *ineffective*, which means simply that the erythropoietic precursors have failed to accomplish their primary task: delivery of mature, enucleated erythrocytes to the circulation. The ferrokinetic profile in this case shows rapid removal of iron from transferrin with delayed entry of label into the pool of circulating red cell hemoglobin. β^+-thalassemia is an important example of this pattern. In β^+-thalassemia, ineffective erythropoiesis is associated with a markedly enhanced PIT.

Intracellular Iron Metabolism

Transferrin and the Transferrin Cycle

Although transferrin was first characterized more than 60 years ago,[95] its receptor eluded investigators until the early 1980s, when monoclonal antibodies prepared against tumor cells were found to recognize the transferrin receptor glycoprotein.[96] Subsequently, receptor-mediated endocytosis of iron bound to transferrin has been characterized in detail. A diagram showing key features of the transferrin receptor is presented in Figure 11-3. Each subunit of the disulfide-linked homodimer contains 760 amino acids.[97-99] Oligosaccharides account for about 5% of the 90-kd subunit's molecular mass.[100] Four glycosylation sites (three *N* linked and one *O* linked) are found in the protein.[101,102] Glycosylation-defective mutants have fewer disulfide bridges, less transferrin binding, and less cell surface expression. The transmembrane domain, located between amino acids 62 and 89, functions as an internal signal peptide because there is none at the N-terminal end.[103] A molecule of fatty acid (usually palmitate) is also covalently linked to each subunit at the internal edge of the transmembrane domain and may play a role in membrane localization. The crystal structure of the ectodomain of the transferrin receptor has been reported.[104] Although no one has yet succeeded in cocrystallizing the receptor with transferrin, molecular modeling and binding studies of mutant transferrin receptor proteins have yielded important insights, including the amino acid residues important for receptor binding to transferrin.[105]

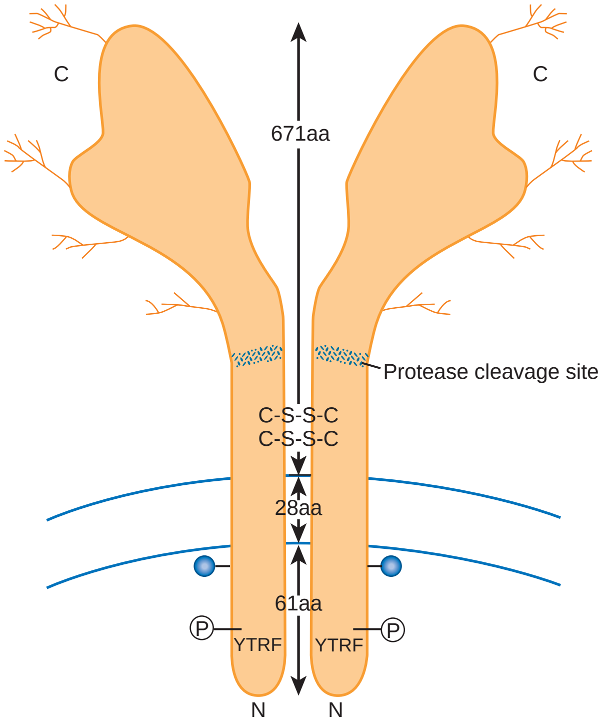

Figure 11-3 Structure of the dimeric transferrin receptor. The N-terminals of both subunits are inside the cell, and the C-terminals are outside. The 61–amino acid *(aa)* intracellular domain has three structural features that appear to play a role in endocytosis: a tyrosine-threonine-arginine-phenylalanine *(YTRF)* amino acid motif, a phosphorylated serine residue *(encircled P)*, and a covalently linked molecule of palmitic acid *(solid circle)*. The transmembrane domain is 28 amino acids long. The extracellular domain has 671 amino acids, including disulfide linkages *(C-S-S-C)*, as well as four glycosylation sites *(branched lines)*. A potential protease cleavage site is located between amino acids 100 and 101.

Iron is taken into cells by receptor-mediated endocytosis of diferric transferrin (Fig. 11-4).[106-109] Receptors on the outer face of the plasma membrane bind iron-loaded

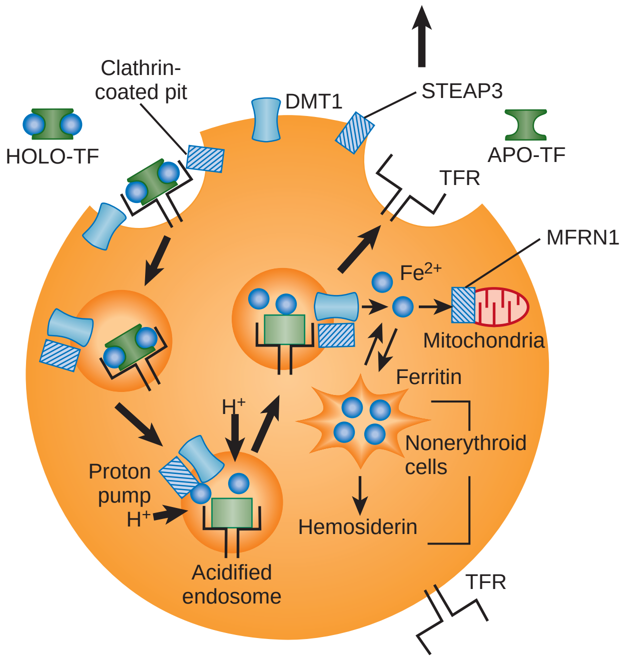

Figure 11-4 The endocytotic transferrin cycle. Apotransferrin *(APO-TF)* binds two atoms of iron per molecule to form diferric transferrin *(HOLO-TF)*. Diferric transferrin binds to the transferrin receptor *(TFR)* on the cell surface. The complex is internalized by invagination of clathrin-coated pits to form specific endosomes. The endosomes import protons, thus lowering the pH within the organelle and decreasing the affinity of transferrin for iron. Liberated iron is translocated through the endosome membrane to the cytoplasm by DMT1 after iron has been reduced from the ferric to the ferrous form by STEAP3. The iron released is shuttled to the mitochondria by mitoferrin 1 (*MFRN1*) for synthesis of heme and to ferritin for storage. The apotransferrin-transferrin receptor complex recycles to the cell surface, where neutral pH promotes release of apotransferrin into serum for reuse. Details are given in the text. *(Modified from Andrews NC: Iron homeostasis: insights from genetics and animal models.* Nat Rev Genet *1:208–217, 2000.)*

transferrin with very high affinity. The C-terminal domain of transferrin appears to mediate receptor binding.[110] Diferric transferrin binds with much higher affinity than monoferric transferrin or apotransferrin does.[111-113] The dissociation constant (K_d) for bound diferric transferrin ranges from 10-7 to 10-9 mol/L at physiologic pH, depending on the species and tissue. The K_d of monoferric transferrin is approximately 10-6 mol/L. The concentration of circulating transferrin is about 25 µmol/L. Therefore, cellular transferrin receptors are ordinarily fully saturated.

After binding to its receptor on the cell surface, transferrin is internalized through a constitutive mechanism that begins with invagination of clathrin-coated pits and the formation of endocytic vesicles. This process requires the short, 61–amino acid intracellular tail of the transferrin receptor molecule.[114-117] Receptors with truncated N-terminal cytoplasmic domains do not recycle properly. This portion of the molecule contains a conserved tyrosine-threonine-arginine-phenylalanine (YTRF) sequence that functions as a signal for endocytosis.

An unknown ATP-dependent proton pump lowers the pH of the internalized endosome to about 5.5.[118-120] Acidification of the endosome weakens the association between iron and transferrin and promotes a conformational change in the transferrin receptor to enhance binding of apotransferrin and facilitate release of iron.[121] An endosomal ferrireductase, STEAP3, reduces iron from the Fe^{3+} state to Fe^{2+}, either at the same time that it is released from transferrin or soon afterward. STEAP3 is a membrane-bound NADPH-dependent oxidoreductase localized to transferrin cycle endosomes and expressed at high levels in erythroid precursors.[122] Related proteins may serve similar functions at other sites.[123]

The iron released from transferrin must exit the endosome and enter the cytoplasm and mitochondria for use in heme biosynthesis, Fe/S cluster biosynthesis, and storage and for other purposes. This transmembrane transport step is also mediated by DMT1.[124,125] DMT1 is unusual in that it is expressed on two very different types of membranes—the apical membrane of intestinal enterocytes and the endosomal membrane of transferrin uptake vesicles in nonpolarized cells. Once transported out of the endosome or across the plasma membrane, iron must be delivered to sites of use or stored in the form of ferritin. The cytosolic chaperone that traffics iron to ferritin appears to be PCBP1, a protein that also functions in the control of mRNA stability and translation, particularly in erythroid cells. In erythroid cells, iron is delivered across the mitochondrial inner membrane by mitoferrin 1 (MFRN1 or SLC25A37)[126]; once across the membrane it is incorporated into heme by the enzyme ferrochelatase.

The fate of transferrin and the transferrin receptor is distinct from that of iron. Rather than entering lysosomes for degradation, as do the ligands in other receptor-mediated endocytosis pathways, intact receptor-bound apotransferrin recycles to the cell surface, where the neutral pH promotes detachment into the plasma. Thus, preservation and reuse of transferrin are accomplished by pH-dependent changes in the affinity of transferrin for iron and the transferrin receptor.[109,118,120] Exported apotransferrin binds additional iron atoms and undergoes further rounds of iron delivery to cells. Thus, a single transferrin molecule, with a half-life of 8 days, may be used hundreds of times for delivery of iron.

It was once a widely accepted belief that the transferrin cycle was important, if not necessary, for the uptake of iron by all mammalian cells. However, two lines of evidence indicate that such is not the case. First, mice and humans with severe deficiencies of plasma transferrin have iron deficiency anemia but vastly increased amounts of iron in nonhematopoietic tissues.[60,127-133] This finding indicates that uptake of iron bound to transferrin is important for red blood cell hemoglobinization and maturation but that transferrin is not essential for delivery of iron to most other tissues. Second, mouse embryos lacking transferrin receptor die midway through gestation as a result of severe anemia, but most nonhematopoietic tissues appear generally intact.[134] Aside from the erythron, only the developing central nervous system shows an apparent requirement for transferrin receptor. In its absence, primitive neuroepithelial cells undergo apoptosis at a greatly increased rate. Taken together, these observations indicate that the transferrin cycle is of primary importance in erythropoiesis and neurogenesis but of lesser importance in other mammalian tissues, at least early in embryonic development.

Non–Transferrin-Bound Iron Uptake

Both hypotransferrinemia and iron overload lead to complete saturation of available plasma transferrin, and non–transferrin-bound iron (NTBI) circulates in a chelatable, low–molecular-weight form (reviewed by Cabantchik and colleagues[135]). This iron is weakly complexed to albumin, citrate, amino acids, sugars, and other small molecules, and it behaves differently from iron associated with transferrin. Nonhematopoietic tissues (particularly the liver, endocrine organs, kidneys, and heart) preferentially take up NTBI. Radiolabeled iron administered to mice with and without available transferrin-binding capacity is distributed in markedly different patterns.[60] In normal animals with excess plasma iron-binding capacity, hematopoietic tissues are the primary sites of uptake. When free transferrin iron-binding sites are absent, however, most iron is deposited in the liver and pancreas, thus indicating that these organs serve as the initial iron reservoirs in the situation of iron overload. Notably, this pattern of distribution is similar to that seen in idiopathic hemochromatosis. NTBI is highly toxic to cells.[136] Plasma NTBI can potentiate the formation of free radicals through the Fenton reaction (see earlier) and thereby induce cell membrane damage. Cardiac cells are particularly susceptible to this damage. Hence, therapeutic chelation must effectively remove plasma NTBI.

The identity or identities of the protein(s) responsible for NTBI uptake are of considerable interest due to the clinical impact of NTBI uptake in hemochromatosis, iron-loading anemias, and chronic transfusion therapy. NTBI uptake activities have been characterized in tissue culture cells, but the physiologically relevant transporters are only beginning to be understood. Topologically, the cell exterior and the endosome interior are equivalent compartments. The primary role of the transferrin–transferrin receptor interaction is to sequester iron near the cell membrane, thereby increasing the likelihood of iron uptake. DMT1 may reside on the plasma membrane of the cell before endocytosis. If so, it should be oriented to transport iron directly into the cell, without the assistance of transferrin (as diagrammed in Fig. 11-4). However, the fact that DMT1 functions only at acidic pH suggests that it probably does not, by itself, account for all NTBI transport. Indeed, hepatocyte DMT1 expression was recently shown not to be essential for hepatocellular iron accumulation in the setting of iron overload.[137] There is some evolving in vivo evidence to suggest that L-type calcium channels,[138,139] or the zinc transporter family (ZIP) proteins ZIP8 and ZIP14 can transport NTBI.[140,141]

ROLE OF IRON IN CELL PROLIFERATION AND DIFFERENTIATION

Iron is indispensable for DNA synthesis and a host of metabolic processes. Iron starvation arrests cell proliferation, presumably because ribonucleotide reductase and other enzymes require the metal.[142] Although transferrin receptors are expressed on all dividing cells in numbers that roughly reflect their growth rate,[143] as discussed in detail earlier, the erythron is the tissue that relies most heavily on delivery of iron by transferrin,. However, the transferrin cycle also appears to play a significant role in other cell types.

Studies of mature T lymphocytes exemplify the general relationship between expression of transferrin receptor and cell proliferation. Transferrin receptors, absent from resting T cells, have long been recognized as markers of T-cell activation. Initiation of cell division by a mitogen such as phytohemagglutinin dramatically increases surface expression of both transferrin receptor and iron uptake.[144] Furthermore, tumor cells upregulate transferrin receptor expression to optimize acquisition of iron for proliferation, and certain monoclonal antibodies against the transferrin receptor curb proliferation of tumor cells in vitro and in vivo.[145-150] Interestingly, some reports have suggested that the transferrin receptor may have an additional role in activated T cells, apart from its iron uptake function. Anti–transferrin receptor monoclonal antibodies have been described that can trigger T-cell activation and secretion of interleukin-2. These antibodies presumably activate a signal transduction pathway beginning with the transferrin receptor but independent of iron trafficking. The transferrin receptor also appears to have a role in early lymphocyte development. Embryonic stem cells in which both transferrin receptor genes have been inactivated fail to differentiate into circulating lymphocytes in vivo in chimeric mice.[151] It is not yet clear whether this is due to defective iron delivery or to perturbation of some other, as yet unknown function of the transferrin receptor.

Chelators that deplete intracellular iron and limit its bioavailability in extracellular fluids further demonstrate the central role of iron in cell proliferation. Agents such as deferoxamine, desferrithiocin, and pyridoxal isonicotinoyl hydrazone inhibit the growth of a variety of tumor cells in culture[152,153] and greatly reduce T-cell proliferation.[154-157] A likely inhibitory mechanism is iron deprivation, with reduced ribonucleotide reductase activity and lower levels of deoxyribonucleotides. This, in turn, leads to mitotic arrest in the S phase of the cell cycle.[158] The addition of iron to the medium reverses the growth inhibition. Chelators may also induce apoptosis, or programmed cell death, through other mechanisms that are not yet understood.

Above all cells, erythroid precursors need an extraordinary amount of iron to support hemoglobin synthesis and differentiation into mature red cells. The density of transferrin receptors on the cell surface is modulated during erythroid development. Transferrin receptors first appear in measurable numbers on colony-forming unit–erythroid (CFU-E) cells and increase to 300,000 per cell on proerythroblasts and as many as 800,000 per cell on basophilic erythroblasts at the time of maximal iron uptake. Numbers then fall to 100,000 per cell on circulating reticulocytes and to negligible levels on mature red cells.[159] A precise correlation exists between iron requirement and transferrin receptor number, thus indicating that the abundance of transferrin receptors on the cell surface is a major determinant of erythroid iron uptake.

In culture, a monoclonal antibody to the transferrin receptor that permits ligand binding but subsequently slows receptor recycling partially blocks erythroid iron uptake. The level of iron uptake is sufficient for cell division but not hemoglobin synthesis.[160]

A wealth of literature demonstrates that oxidized heme (hemin) promotes differentiation of erythroleukemia cell lines in tissue culture.[161-164] Conversely, deficient heme biosynthesis abrogates chemical induction of differentiation in an erythroleukemia cell line subclone.[164] Heme regulates the transcription of globin, transferrin receptor, and ferritin genes.[165-167] Some of these effects may be mediated by the heme-dependent transcriptional repressor BACH1.[168,169] A second, major mechanism in which heme regulates terminal erythroid differentiation is mediated by a heme-dependent elongation factor 2a kinase termed heme-regulated kinase (HRI), which globally suppresses translation in erythroid cells in the absence of heme (reviewed by Chen[170]). Although some of the precise mechanisms remain to be elucidated, it is clear that iron uptake, heme biosynthesis, and globin protein production are coordinately regulated. Interrelated regulatory networks apparently allow red cell precursors to maximize hemoglobin formation without accumulating excess globin proteins, unbound iron, or toxic protoporphyrin intermediates.

REGULATION OF PROTEINS OF IRON METABOLISM

Ferritin

Once inside the cytoplasm, iron is almost certainly bound by carrier molecules that assist in delivering iron to intracellular locations, including mitochondria (for heme biosynthesis) and ferritin (for storage). The identities of the intracellular iron carrier molecules by and large remain unknown. However, there is recent evidence to suggest that poly-C–binding protein 1 (PCBP1), which is involved in mRNA stability and translation, also serves as an iron chaperone specific for iron acquisition by ferritin and the hypoxia-inducible factor (HIF) prolyl hydroxylase.[171-173] The amount of iron in transit within the cell at any given time is small and difficult to measure. This minute pool of transit iron, which is believed to be in the Fe^{2+} oxidation state, is the biologically active and potentially toxic form of the element. Metabolically inactive iron, stored in ferritin and hemosiderin, is nontoxic and in equilibrium with this exchangeable transit iron.

Both prokaryotes and eukaryotes produce ferritin molecules for iron storage. Mammalian ferritin molecules are complex 24-subunit heteropolymers of H (for heavy or heart) and L (for light or liver) protein subunits. L subunits are 19.7 kd in mass, with isoelectric points of 4.5 to 5; H subunits are 21 kd in mass, with isoelectric points of 5 to 5.7. The subunits of the ferritin molecule probably arose by gene duplication, although the degree of nucleotide sequence homology between the two is only about 50%. They assemble to form a sphere with a central cavity in which up to several thousand atoms of crystalline iron can be stored in the form of poly-iron-phosphate oxide.[174] Eight channels through the sphere are lined by hydrophilic amino acid residues, and six more are lined by hydrophobic residues.[175] Strong interspecies amino acid conservation is seen in the residues that line the hydrophilic channels, whereas marked variation is seen in those along the hydrophobic passages. The hydrophilic channels terminate with aspartic acid and glutamic acid residues and are lined by serine, histidine, and cysteine residues, all of which potentially bind metal ligands.

Although the two ferritin chains are homologous, only H ferritin has ferroxidase activity, which is essential for iron incorporation into the ferritin polymer.[176,177] Isoelectric focusing shows that ferritin polymers have a variable composition of H and L subunits. These isoferritins, as they are called, show tissue-specific variation. Ferritin from liver, for instance, is rich in L subunits, as is that from the spleen. In contrast, the heart has ferritin rich in H subunits. Increased H-subunit content correlates with increased iron use, whereas increased L-subunit content correlates with increased iron storage.[178] The ratio of H to L subunits increases with increased cell proliferation.[179] Thus, ferritin provides a flexible reserve of iron.

Despite the fact that it does not, itself, have enzymatic activity, a mutation in L ferritin has been shown to cause a distinctive iron deposition disease in humans termed *neuroferritinopathy*. In patients carrying a nucleotide insertion altering the carboxy-terminus of L ferritin, iron overload develops in the basal ganglia and leads to a neurodegenerative disease with variable extrapyramidal features.[180] By contrast, pathologic accumulation of apo-L-ferritin leads to a distinctive form of hereditary cataracts (hereditary hyperferritinemia-cataract syndrome) that is unassociated with iron metabolism abnormalities (see below). A number of other disorders, including aceruloplasminemia (see below), as well as pantothenate kinase deficiency, can also lead to pathologic iron deposition in distinctive regions of the brain.

Ferritin molecules aggregate into clusters that are engulfed by lysosomes and degraded. The end product of this process, hemosiderin, is an amorphous agglomerate of partially denatured protein and lipid interspersed with iron oxide molecules.[181] In cells overloaded with iron, lysosomes accumulate large amounts of hemosiderin, which can be visualized by Prussian blue (Perls) staining. Although the iron enmeshed in this insoluble compound constitutes an end-stage product of cellular iron storage, it remains in equilibrium with cytosolic ferritin. Ferritin iron, in turn, is in equilibrium with iron complexed to low–molecular-weight carrier molecules. Therefore, introduction of an effective chelator into the cell captures iron from the low–molecular-weight "toxic" iron pool, draws iron out of ferritin, and eventually depletes iron from hemosiderin as well, though only very slowly. As might be expected, the bioavailability of hemosiderin iron is much lower than that of iron stored in ferritin.

The large number of processed pseudogenes that exist for each subunit initially confounded pinpointing the chromosomal location of ferritin genes. Functional ferritin genes for the H and L subunits are located on human chromosomes 11 and 19, respectively.[182] In addition, there is an intronless gene encoding a mitochondrial, H-like ferritin molecule located on human chromosome 5q.[183] The function of mitochondrial ferritin remains uncertain, although the fact that its expression is increased in erythroid precursors from patients with sideroblastic anemia suggests that it is involved in mitochondrial iron management.[183,184]

Ferritin formation is controlled at multiple levels—transcription, message stabilization, translation, and subunit assembly. In the liver and in HeLa cells, iron rapidly induces the synthesis of L-subunit mRNA, with no effect on H-subunit transcription.[185,186] In contrast, induced differentiation of HL-60 promyelocytic leukemia cells and mouse erythroleukemia cells increases production of H-subunit mRNA.[187,188] Tumor necrosis factor induces H-chain transcription in human myoblasts.[189] Iron, heme, reactive oxygen species, and oxidative stress all enhance transcription and translation of the ferritin heavy chain (reviewed by Rouault[190]).

Cytoplasmic ferritin mRNA forms a stable complex with several proteins. Both iron and interleukin-1β enhance translation of ferritin mRNA.[191] Influx of iron into cells shifts the message onto the ribosomes, thereby enhancing the synthesis of ferritin subunits.[192] This translational control mechanism involves an RNA-protein interaction that links the expression of genes encoding ferritin, the transferrin receptor, enzymes of heme biosynthesis, DMT1, ferroportin, and other proteins. Zahringer, Baliga, and Munro[192] initially showed that ferritin synthesis was regulated at the level of message translation. Comparison of the 5′untranslated regions of ferritin mRNA encoding both heavy and light chains showed striking conservation of a 28-bp sequence motif that was predicted to form a stable RNA stem-loop structure and was necessary for translational control of ferritin (Fig. 11-5, inset).[193,194]

Subsequently designated the iron response element (IRE), this RNA stem-loop is recognized by at least two specific RNA-binding proteins called IRP1 and IRP2 for iron regulatory proteins 1 and 2. IRP1 is a 98-kd soluble polypeptide with homology to the mitochondrial tricarboxylic acid–cycle enzyme aconitase (ACO1).[195,196] Indeed, IRP1 is the cytoplasmic isozyme of aconitase. Like mitochondrial aconitase, the enzymatic active site of IRP1 contains a 4Fe/4S cluster. When the iron concentration in the cytosol is high, the cluster is complete and the protein is in its holoenzyme form and possesses aconitase activity and cannot bind mRNA. Under these conditions, the ferritin message is translated efficiently. Conversely, when the iron concentration is low, the protein is in its apo-form and aconitase activity is absent, RNA binding is avid, and ferritin message translation is blocked because translation initiation complexes cannot form properly.[197-202] Thus, IRP1 is a dual-function protein, with ambient iron controlling the switch by assembly and disassembly of a 4Fe/4S cluster. Other molecules that modulate the switch include ascorbic acid, nitric oxide, and heme, all of which contribute to the oxidation status of the cell.[203-205] This mechanism allows ferritin protein expression to be rapidly

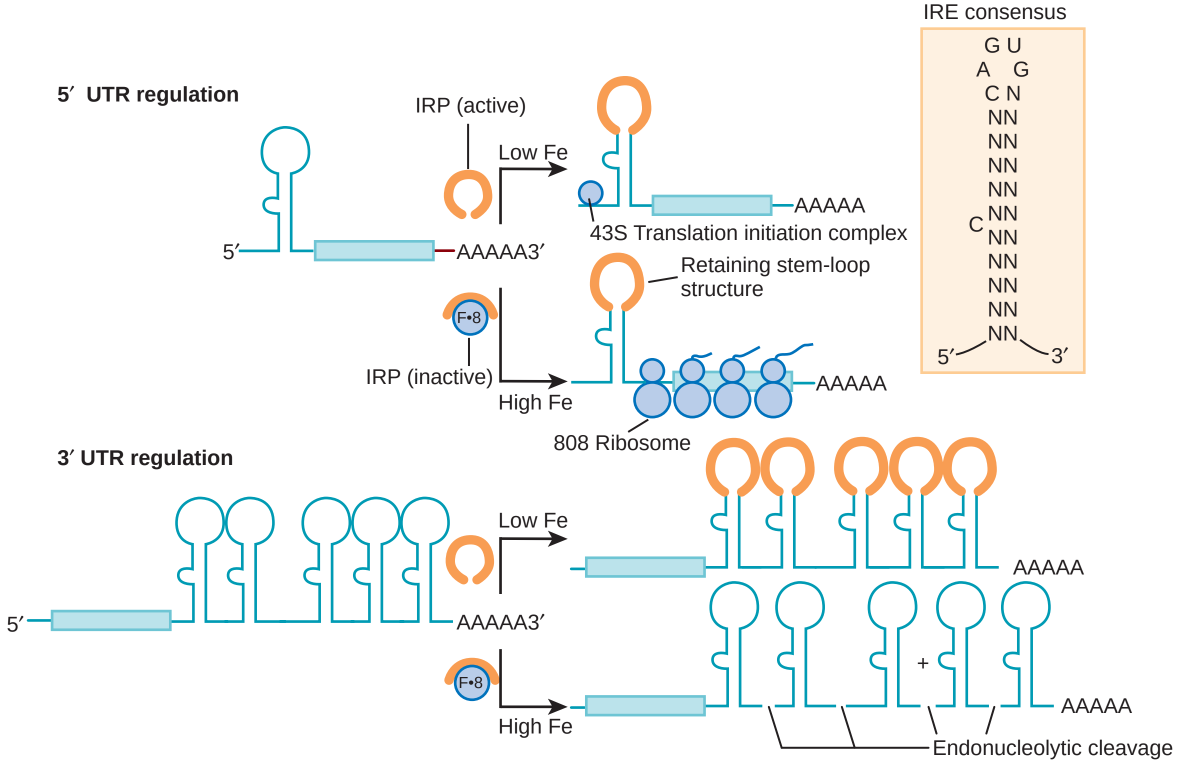

Figure 11-5 Iron response element *(IRE)*/iron regulatory proteins *(IRP)* regulation. Two mechanisms of action of IRPs are shown. An IRP molecule binds to an IRE stem-loop structure located in the untranslated regions *(UTRs)* of messenger RNA sequences. A consensus IRE structure is shown in the *inset*. Under low-iron or heme conditions, IRPs bind avidly to RNA. With abundant iron, no binding occurs. Binding of IRP to IRE elements in the 5′ UTR blocks translation. In contrast, binding of IRPs to 3′ UTR IRE elements protects messenger RNAs from degradation.

downregulated without degradation of mRNA. The importance of IRP-mediated translational control is underscored by the fact that plasma hyperferritinemia and ferritin-containing cataracts develop in patients with mutations in the L-ferritin IRE.[206,207] Nevertheless, these patients with hereditary hyperferritinemia cataract syndrome do not have abnormalities in iron homeostasis.[208,209] Furthermore, it appears that an iron overload disorder resembling hereditary hemochromatosis develops in rare patients with mutations in the H-ferritin IRE, presumably because increased H-ferritin expression leads to increased cellular iron assimilation or retention, or both.[210]

A second IRE-binding protein, IRP2, also modulates posttranscriptional expression of mRNA by binding to IREs in much the same way. Initially isolated in the liver, IRP2 has been found in all tissues examined and is more abundant than IRP1 in some.[211,212] IRP2 lacks aconitase activity[211] and does not contain an Fe/S cluster to function as an iron sensor. Rather, IRP2 protein levels are modulated directly by iron or by heme and the molecule is actively degraded when iron or heme (or both) is abundant.[213-216] Recently, it has been shown that an E3 ubiquitin ligase complex that contains FBXL5 controls IRP2 protein abundance by targeting it for proteasomal degradation. FBXL5 contains an iron- and oxygen-binding hemerythrin domain that acts as a ligand-dependent regulatory switch that mediates the stability of FBXL5 under iron- and oxygen-replete conditions.[217,218]

The Transferrin Receptor

IRPs also modulate expression of the transferrin receptor gene. The gene encoding the transferrin receptor is located on human chromosome 3q26.2-qter, near the gene encoding transferrin at 3q21.[219] It consists of 19 exons spread over 31 kb.[220] The transferrin receptor mRNA is approximately twice the length needed to encode the receptor protein. Its lengthy 3′untranslated region contains five RNA stem-loop structures that are structurally similar to those of the ferritin IREs.[221-223] IRP binding to these sites increases the stability of the transferrin receptor message by obscuring an endonucleolytic cleavage site (see Fig. 11-5).[224] The result is a larger amount of transferrin receptor mRNA in the cell. A deficit of cellular iron raises transferrin receptor mRNA levels at least in part through enhanced message stability. However, IRE regulation is probably not responsible for the primary increases in transferrin receptor number in erythroid cells, because this occurs at the transcriptional level and is unaffected by iron status. Relatively little is understood about the tissue-specific transcriptional regulation of the transferrin receptor.[225]

The versatile regulatory functions of IREs may also confer iron-dependent regulation on other proteins. IREs are present in the 5′ untranslated regions of the mRNA encoding the erythroid form of the heme biosynthetic enzyme δ-aminolevulinic acid synthase, mitochondrial aconitase, and ferroportin.[30,31,33,226-228] A single 3′ IRE is found in one splice isoform of DMT1 mRNA.[229] As the rate-limiting enzyme in heme biosynthesis, the IRE in the erythroid form of δ-aminolevulinic acid synthase produces a conceptually satisfying link between iron and heme production. However, the functions of the IREs in the other mRNAs are not yet understood. It is postulated that all IREs serve the common purpose of coupling changes in the iron status of the cell with its ability to use and store the element (see Fig. 11-5). When the intracellular iron concentration is low, the IRE of ferritin mRNA binds IRP and reduces ferritin synthesis because additional iron storage capacity is not needed in this circumstance. Simultaneously, the level of transferrin receptor mRNA increases as the IRP stabilizes the message, thereby increasing expression of the transferrin receptor. Together, these events increase the flow of iron into cells while protecting against iron toxicity. When iron levels in the cell are high, the opposite scenario is operative. Although the IRPs accomplish these regulatory feats under extremes of iron status, the importance of IREs and IRPs in modulating gene expression in normal humans and animals is not fully understood. Recently, novel IRE-containing genes have been identified, with roles less directly related to iron homeostasis.[230-232]

In an attempt to sort out the unique functions of IRP1 and IRP2 and to evaluate their roles in vivo, targeted mutagenesis was used to generate mutant mice lacking each of the proteins.[233-238] Initial characterization of IRP1 knockout mice indicated that they had no identifiable defects, but more recent studies have shown that the animals have a transient polycythemia that is associated with an elevated erythropoietin level due to dysregulation of HIF-2α translation, providing further evidence for crosstalk between hypoxia-sensing and iron-regulatory pathways.[239-241] IRP2 knockout mice have abnormalities in several tissues. Initially, the most striking aspect of the IRP2 knockout phenotype was a late-onset neurologic disorder associated with abnormal deposition of iron in white matter tracts and nuclei throughout the brain.[236] The mice demonstrated ataxia, bradykinesia, and tremors. However, these findings could not readily be explained by known activities of IRP2, and a second group reported that an independently targeted line of mice did not have obvious neurodegeneration.[235] It is possible that the discrepancy may be explained by differential severity of a neurologic phenotype on different genetic backgrounds. More recently, both groups have reported that IRP2-deficient mice have mild microcytosis and erythropoietic protoporphyria as well as subtle perturbations in systemic iron homeostasis.[233,242]

Serum Ferritin and Soluble Transferrin Receptors

Although most ferritin is located within cells, a measurable amount of the protein exists in serum. Intracellular concentrations, particularly in the liver, are several orders of magnitude higher than serum concentrations. Therefore, a small amount of cellular lysis could liberate a relatively large amount of ferritin. However, nearly all serum ferritin appears to be secreted. There are probably several cell types that are sources of secreted extracellular ferritin, including iron-recycling macrophages and hepatocytes. Circulating ferritin consists almost exclusively of L-chain subunits.[243] In contrast, intracellular ferritin contains a mixture of H and L subunits. In addition, unlike intracellular ferritin, circulating ferritin is glycosylated, thus suggesting that it passes through the endoplasmic reticulum and Golgi apparatus in a manner similar to that of other secreted proteins.

Serum ferritin levels decline with iron deficiency and rise with iron overload.[244] In the absence of severe liver disease, infection, or chronic inflammation, serum ferritin is roughly proportional to total body iron stores. The correlation between serum ferritin levels and body iron stores is useful in the evaluation of patients with possible iron deficiency or iron overload. A low serum ferritin level (<12 μg/L) invariably represents iron deficiency, and high serum ferritin levels are found in patients with iron overload. Extremely high serum ferritin levels should be interpreted cautiously, however, because the correlation between ferritin levels and body iron stores is approximately linear only for storage reserves of iron ranging between 1 and 3 g. In addition, normal circulating ferritin values vary with sex and age. These considerations must be factored into any evaluation of iron stores based on ferritin values, particularly in children.

Various conditions modify serum ferritin levels. Inflammation increases the serum ferritin concentration severalfold.[245] Infections, particularly chronic conditions such as tuberculosis or osteomyelitis, may also increase levels substantially, presumably because of the associated inflammatory response. Autoimmune disorders, chronic renal disease, and chronic liver disease are likewise associated with elevated levels. A number of tumors are variably associated with an increased level of circulating ferritin. For example, ferritin is an important prognostic factor in childhood neuroblastoma, in which serum ferritin levels correlate with disease severity.[246]

The mechanisms by which inflammation and tumors increase the quantity of plasma ferritin are not fully understood. Treatment with interleukin-1β, a prime mediator of the inflammatory response, increases synthesis of ferritin in human hepatoma cells,[191] whereas tumor necrosis factor has been shown to increase ferritin mRNA levels in murine cells in culture.[189] These cytokines may also increase ferritin synthesis in cells secreting the protein. In addition, the inflammatory cytokine interleukin-6 induces hepcidin expression,[47] which results in increased macrophage iron storage and probably contributes to increased serum ferritin levels. Furthermore, serum ferritin elevated out of proportion to iron stores and the transferrin saturation is a hallmark feature of ferroportin disease (see later).[247]

Soluble transferrin receptors are also found in serum. Small vesicles containing transferrin receptors are shed from reticulocytes during their maturation to erythrocytes.[248] In addition to these vesicle-associated receptors, the extracellular portion of the transferrin receptor lacking its transmembrane anchor can be found in the circulation.[249-251] One mechanism by which soluble transferrin receptors are generated is a membrane-associated protease activity that clips the molecule between amino acids 100 and 101, at the base of its extracellular stem.[252,253] This cleavage is potentiated by mutation of an *O*-linked glycosylation site at amino acid 104, thus suggesting that differential glycosylation may play a regulatory role.[254] The transferrin-binding domain is intact in these soluble receptors, and they are likely to be complexed with transferrin in serum.

Because maturing red cells shed their transferrin receptors, the amount of soluble transferrin receptor in plasma reasonably reflects the degree of erythropoiesis. Measurement of plasma levels of soluble transferrin receptor provides a means of estimating erythropoietic activity that is simpler than the relatively cumbersome PIT determination.[255] Soluble transferrin receptor (sTfR) is present in substantially lower amounts in patients with aplastic anemia relative to normal individuals. In contrast, values in patients with anemia caused by ineffective erythropoiesis are markedly increased. Patients with iron deficiency also have increased levels of circulating soluble transferrin receptors. This may result in part from the increase in cellular transferrin receptor expression produced by iron starvation and in part from the increased erythroid turnover associated with the ineffective erythropoiesis of iron deficiency. sTfR and serum ferritin values can be considered together as the ratio of sTfR to the log of ferritin (sTfR-F index). Values greater than 1.5 suggest iron deficiency alone or in combination with an inflammatory condition; values less than 1.5 are characteristic of the anemia of chronic inflammation.[256] The sTfR-F index also appears to be sensitive enough to detect iron deficiency before iron-restricted erythropoiesis is clinically apparent.[257] sTfR and the sTfR-F index are both decreased in patients with iron overload.[258,259]

EXTREMES OF IRON BALANCE

Iron disorders are invariably abnormalities in iron balance or distribution, or both. Iron deficiency is primarily due to acquired causes. In contrast, primary iron overload usually results from genetic abnormalities that perturb the regulation of intestinal iron absorption. Disorders affecting other steps in transport may be manifested as inappropriate iron accumulation in some tissues and iron deficiency in other tissues.

Iron Deficiency

Epidemiology of Iron Deficiency

Iron deficiency is the most frequent and widespread nutritional deficiency in the world[260] because it is common in developing and developed countries alike. In fact, iron deficiency is the only micronutrient deficiency that is prevalent in virtually all developed countries.[260] To this end, one of the U.S. national health objectives for 2010 was to reduce iron deficiency in vulnerable populations such as toddlers and women of childbearing age by 3% to 4%.[261]

Increasing rates of breast-feeding and the availability of iron-fortified formula (see later), in conjunction with initiatives such as the U.S. Special Supplemental Food Program for Women, Infants and Children and the American Academy of Pediatrics' promotion of formula in place of cow's milk, have greatly reduced the prevalence of iron deficiency *anemia* in infants in developed countries. Nonetheless, iron deficiency, both with and without anemia, remains relatively common. According to the Fourth National Health and Nutrition Examination Survey (NHANES IV), iron deficiency without anemia exists in 7% of toddlers aged 1 to 2 years, 9% of adolescent girls, and 16% of women of childbearing age.[262] Adolescents participating in strenuous training are another pediatric subpopulation at risk for iron deficiency. For example, young military recruits and elite adolescent athletes have an increased risk of nonanemic iron deficiency.[263-265]

Socioeconomic factors are associated with iron deficiency anemia in children. For example, infants and children of low-income and minority backgrounds have higher documented rates of iron deficiency anemia.[266,267,268] Although food insecurity is known to be associated with iron deficiency anemia,[269] other factors such as bottle-feeding patterns may also play a role in the prevalence of iron deficiency.[270] The iron status of young children correlates closely with the iron status of their mothers, thus indicating that a constellation of factors in the child's environment influence iron intake and therefore iron status.[271]

Phases of Development of Iron Deficiency

Because most of the body's iron is directed toward synthesis of hemoglobin, erythrocyte production is among the first casualties of iron deficiency to become clinically apparent in usual laboratory evaluations. However, it actually represents a late stage of iron depletion. Iron deficiency progresses through three discernible phases:

1. *Prelatent iron deficiency* occurs when tissue stores are depleted, without a change in hematocrit or serum iron levels. This stage of iron deficiency may be detected by low serum ferritin measurements.

2. *Latent iron deficiency* occurs when reticuloendothelial macrophage iron stores are depleted. The serum iron level drops and TIBC increases without a change in hematocrit. This stage may be detected by a routine check of fasting, early-morning transferrin saturation. Erythropoiesis begins to be limited by a lack of available iron, and sTfR levels increase. The reticulocyte hemoglobin content (CHr) decreases because newly produced erythrocytes are iron deficient.[272] The bulk of the erythrocyte population appears normal. For this reason, sole reliance on indicators derived from the entire erythrocyte population frequently fails to detect this stage of iron deficiency.[272,273]

3. *Frank iron deficiency* anemia is associated with erythrocyte microcytosis and hypochromia. It is detected when iron deficiency has persisted long enough that a large proportion of the circulating erythrocytes were produced after iron became limiting.

Etiology of Iron Deficiency

The development of iron deficiency is a result of the interaction between iron intake, physiologic iron requirements, and the potential for blood loss.

Inadequate Iron Intake

Dietary Sources. Heme, derived from animal tissues, is the most readily absorbed form of iron. Uptake occurs independently of gastric pH and, like the uptake of nonheme iron, is increased in patients with high marrow erythroid activity. Much of the world's population eats little or no meat; for these peoples, nutrition is derived from cultivated grasses such as rice, plants that are relatively poor sources of iron.[22] Eating such a diet is one of the factors that make iron deficiency anemia the most common nutritional anemia worldwide.

In developing countries, nutritional iron deficiency is often compounded by chronic blood loss from parasitic infections and malaria (see later). In industrialized countries, however, iron deficiency is usually due to insufficient dietary intake to meet physiologic needs. Because of their rapid growth and increased need for iron, infants, toddlers, female adolescents, and pregnant women are especially vulnerable.

Consumption of cow's milk may contribute to iron deficiency through several mechanisms. Cow's milk and human milk both have low iron content, but the bioavailability of iron in human milk is greater.[274] Therefore, the transition from human milk to cow's milk may place toddlers at risk for iron deficiency. Indeed, the prevalence of iron deficiency increases with the duration of bottle-feeding of cow's milk.[270] Cow's milk also compounds iron deficiency by replacing iron-rich foods in the diet. In addition, components of cow's milk, such as calcium and caseinophosphopeptide, can directly interfere with iron absorption.[275,276] Furthermore, whole cow's milk contains proteins that may irritate the lining of the gastrointestinal tract in infants, and even low-grade but chronic hemorrhage may produce significant iron deficiency.[277] The neonatal growth spurt requires a tremendous quantity of iron, thus compounding the disadvantages of cow's milk. For these reasons, current recommendations exclude cow's milk from the infant's diet in the first year of life, limit subsequent consumption of cow's milk to 24 ounces per day, suggest that nonbreastfed infants should receive iron-fortified formulas, and advise an additional source of iron for infants who are breastfed after 4 to 6 months of age, when they have depleted the excess iron that was present in newborn stores and erythrocytes.[278,279]

Poor Bioavailability. Although iron is abundant in the environment, it is nearly insoluble in aqueous solution, which makes acquisition of the common element a major challenge. Most environmental iron exists as insoluble salts. Gastric acidity assists in conversion to absorbable forms, but the efficiency of this process is limited.[280] Many plant products contain iron, but absorption frequently is limited both by low solubility and by powerful natural chelators that bind ambient iron. Phytates (organic polyphosphates) found in wheat products, for example, bind iron with tremendous avidity. The challenge of acquiring sufficient iron from the environment may have been an important factor in the spread of genes for hemochromatosis disorders.

High gastric pH reduces the solubility of inorganic iron and thereby impedes absorption. Surgical interventions, such as vagotomy or hemigastrectomy for peptic ulcer disease, formerly were the major causes of impaired gastric acidification with secondary iron deficiency, particularly in adults. The histamine H_2 blockers and the more recently introduced acid pump blockers, used to treat peptic ulcer disease and acid reflux, may cause defective iron absorption.[281,282] There is, however, little evidence that they substantially alter iron status in those without preexisting iron deficiency.[283-285]

The impaired function of gastric parietal cells associated with pernicious anemia not only reduces the production of intrinsic factor but also lessens gastric acidity and hence compromises absorption of iron. In addition, megaloblastic enterocytes absorb iron poorly. Frank iron deficiency can accompany the anemia produced by cobalamin deficiency.[286-288] However, the rarity of pernicious anemia in children makes this complication uncommon in pediatric populations.

A number of environmental factors can produce dietary iron deficiency by interfering with iron absorption, including metals such as cobalt, which share the iron absorption machinery. Lead may fall into this category, although it remains to be definitively established whether DMT1 is the primary intestinal lead transporter in vivo.[26] Regardless of the mechanism, it is clear that iron deficiency increases the rate of uptake of both iron and lead from the gastrointestinal tract. Iron deficiency and lead intoxication frequently coexist.

Malabsorption. Some disorders disrupt the integrity or surface area of the enteric mucosa and thereby hamper iron absorption (Box 11-2). Consequently, in the absence of blood loss (see below), iron deficiency unresponsive to oral iron therapy should prompt an investigation for intestinal diseases that affect the duodenum. Inflammatory bowel disease, particularly Crohn disease, may injure extensive segments of the small intestine, including the jejunum and duodenum. Invasion of the submucosa by inflammatory cells and disruption of the tissue architecture impair iron absorption and uptake of dietary nutrients.[289] Occult gastrointestinal bleeding exacerbates the problem. The result is iron deficiency anemia complicated by the anemia of chronic inflammation. Furthermore, Crohn disease frequently involves the terminal ileum, with the concurrent development of cobalamin deficiency. These disorders are not diagnostic enigmas. Patients with extensive bowel involvement are very ill. Diminishing the underlying inflammatory process best treats the iron deficiency.

Tropical sprue and celiac disease (gluten-sensitive enteropathy) can also interfere with iron absorption.[289] Loss of the villous absorptive surface along with chronic inflammation causes profound malabsorption, although some patients with deranged iron absorption lack gross or even histologic changes in the structure of the bowel mucosa. The anemia in these patients is often complicated by a superimposed, generalized nutritional deficiency.[290] Celiac disease frequently improves with ingestion of a gluten-free diet, with secondary correction of the anemia.

Iron absorption may be disrupted when substantial segments of bowel, particularly the proximal duodenum, are removed surgically. Intractable inflammatory bowel disease, traumatic abdominal injury, and structural complications such as intestinal volvulus or intussusception all may necessitate intestinal resection. Likewise, obesity surgeries that bypass the proximal duodenum may limit iron absorption. Iron deficiency develops slowly afterward and may not become evident for several years after the surgical procedure.

Box 11-2 **Causes of Iron Deficiency Anemia**

- INADEQUATE ABSORPTION
  - Poor bioavailability (absorption of heme Fe > Fe^{2+} > Fe^{3+})
  - Antacid therapy/high gastric pH
  - Bran, tannins, phytates, starch
  - Other metals (e.g., cobalt, lead)
  - Loss or dysfunction of absorptive enterocytes (e.g., gluten-sensitive enteropathy, gastric bypass, Crohn disease)
- INSUFFICIENT OR INACCESSIBLE IRON STORES
  - Physiologically Increased Requirements
  - Pregnancy, particularly repeated
  - Rapid growth (e.g., infancy)
  - Gastrointestinal Blood Loss
    - Epistaxis
    - Gastritis
    - Ulcer
    - Meckel diverticulum
    - Milk-induced enteropathy
    - Parasitosis
    - Varices
    - Tumor or polyps
    - Inflammatory bowel disease
    - Arteriovenous malformation
    - Colonic diverticula
    - Hemorrhoids
  - Vaginal Blood Loss
    - Increased menstrual blood loss
    - Tumor
  - Urinary Blood Loss
    - Chronic intravascular hemolysis (e.g., paroxysmal nocturnal hemoglobinuria)
    - Chronic glomerulonephritis
    - Chronic infection
    - Tumor
  - Pulmonary Blood Loss
    - Pulmonary hemosiderosis
    - Tuberculosis
    - Bronchiectasis
  - Inflammation or Infection
  - Defects in intestinal iron uptake (e.g., *TMPRSS6* mutations)
- INADEQUATE PRESENTATION TO ERYTHROID PRECURSORS
  - Atransferrinemia
  - Anti–transferrin receptor antibodies
- ABNORMAL INTRACELLULAR TRANSPORT OR UTILIZATION
  - Erythroid iron-trafficking defects (e.g., *DMT1* mutations)
  - Defects in heme biosynthesis

Malabsorption of iron is rare in the absence of gross or microscopic structural defects of the intestine or the anemia of chronic inflammation (see later). However, multiple families with an autosomal recessively inherited predisposition to iron deficiency and systemic iron malutilization have been described.[291-293] These individuals exhibit iron deficiency anemia at an early age that is characterized by a nearly complete lack of response to oral iron supplementation and a slow, incomplete response to parenteral iron therapy—so-called iron-refractory, iron deficiency anemia (IRIDA). Individuals with IRIDA have biallelic inactivating mutations in the TMPRSS6 protein, a transmembrane serine protease expressed in the liver, that leads to inappropriate hepcidin overexpression and eventuates in impaired iron absorption and iron recycling (Fig. 11-6).[294-296] Importantly, a

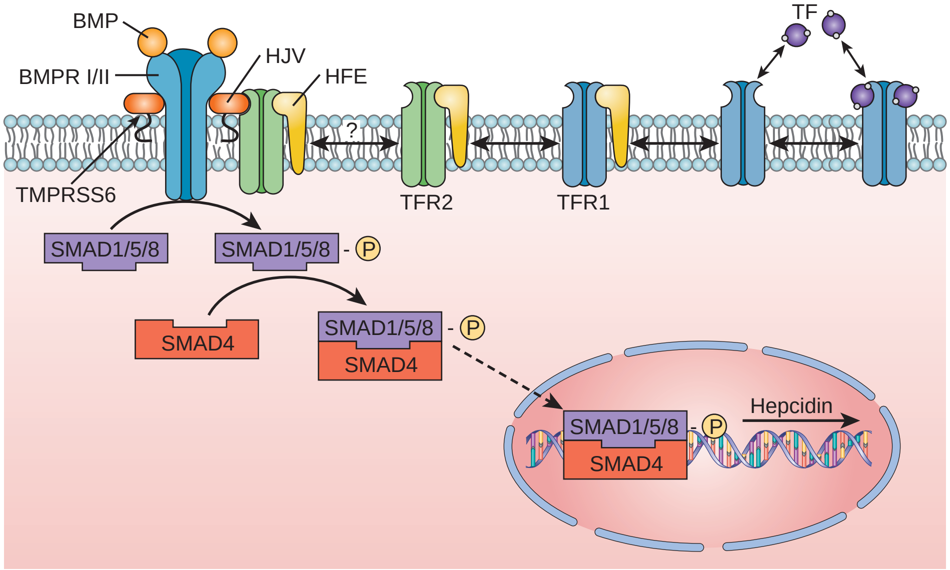

Figure 11-6 Iron-dependent BMP signaling. Transferrin receptor 1 *(TFR1)*; the autosomal recessive hereditary hemochromatosis proteins HFE, transferrin receptor 2 *(TFR2)*, and hemojuvelin *(HJV)*; as well as the bone morphogenetic protein receptor type I and II *(BMPR I/II)* complex are associated with the cell surface. HFE associates with TFR1 and TFR2 in an equilibrium modified by the concentration of holotransferrin *(TF)*. It has been suggested that HFE and TFR2 can further associate with the HJV-BMPR I/II signaling complex to modify BMPR signaling mediated by phosphorylation upon sons of mothers against decapentaplegic homologues *(SMADs)* 1, 5, and 8. Association of phosphorylated SMAD1/5/8 with a common co-SMAD, SMAD4, leads to translocation of the complex into the nucleus and stimulation of hepcidin *(HAMP)* gene expression. TMPRSS6 cleaves HJV to down-regulate the hepcidin response to any given plasma holotransferrin concentration. *(Modified from Fleming MD: The regulation of hepcidin and its effects on systemic and cellular iron metabolism.* Hematology Am Soc Hematol Educ Program *151-8, 2008.)*

common single-nucleotide polymorphism (SNP) in the protein-coding region of TMPRSS6 (a substitution of a valine for an alanine at amino acid position 736) is strongly associated with lower plasma iron and ferritin levels as well as several red blood cell parameters,[297-300] and has been shown to modify the severity of disorders of iron overload.[301] Although mutations in DMT1 might also be expected to, and in model organisms do indeed,[25,125,302] lead to a somewhat similar congenital iron deficiency anemia phenotype as mutations in TMPRSS6; in fact, reported patients with DMT1 mutations have iron-restricted erythropoiesis in the setting of systemic iron overload.[303-307]

Systemic Iron Loss

Gastrointestinal Blood Loss. Blood loss is the leading cause of iron deficiency worldwide. The gastrointestinal tract is both the site of iron uptake and the most common site of blood loss, particularly when bleeding is not readily apparent. However, bleeding from other sites should also be considered if iron deficiency has not otherwise been explained.

Anatomic defects of the gastrointestinal tract commonly cause blood loss and consequent iron deficiency. The most frequent congenital defect is Meckel diverticulum, which results from a persistent omphalomesenteric duct. This abnormality can produce abdominal pain and, occasionally, intestinal obstruction in young children. Meckel diverticulum may equally be associated with clinically overt or occult blood loss and secondary iron deficiency.[308] Peptic ulcer disease is extremely uncommon in children but should be considered as a cause of gastrointestinal blood loss when the clinical setting suggests it.

Other structural defects of the gastrointestinal tract may cause bleeding as well. Arteriovenous malformations involving the superficial blood vessels occur in patients with hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome). These defective vessels frequently bleed to a degree that engenders iron deficiency. Although the disorder is transmitted as an autosomal dominant trait, the characteristic vascular lesions rarely attain clinical significance before young adulthood. The condition is easily recognized because the mucosal lining of the oropharynx and nasal cavity exhibits characteristic telangiectasias.

The leading cause of gastrointestinal blood loss worldwide is parasitic infestation. Hookworm infection, caused primarily by *Necator americanus* or *Ancylostoma duodenale*, is endemic in much of the world and is often asymptomatic. Microscopic blood loss leads to significant iron deficiency, particularly in children.[309] More than 1 billion people, most in tropical or subtropical areas, are infested with parasites. Combined, their total daily blood loss exceeds 11 million liters. The larvae spawn in moist soil and penetrate the skin of unprotected feet. Hookworm infection, once prevalent in the southeastern United States, declined precipitously with better sanitation and routine use of footwear when outside.

Trichuris trichiura, the culprit in trichuriasis or whipworm infection, is believed to infest the colon of 600 to 700 million people. Only 10% to 15% of these individuals have worm burdens sufficiently great to produce clinical disease. However, most are children between the ages of 2 and 10 years. Growth retardation, in addition to iron deficiency, occurs with heavy infestation.[310] Trichuriasis is the most common helminthic infection encountered in Americans returning from visits to tropical or subtropical regions of the world.

Urinary Blood Loss. Occasionally, blood loss into the urinary tract outstrips iron absorption. However, urinary blood loss is usually apparent and sufficiently alarming that patients seek medical attention before substantial iron deficiency develops. Iron deficiency resulting from hematuria secondary to renal disease is relatively uncommon.

The best characterized cause of significant renal blood loss is Berger disease, which produces relapsing episodes of gross or microscopic hematuria. The disorder occurs most commonly in older children and young adults. It is characterized by diffuse mesangial proliferation or focal and segmental glomerulonephritis. Diffuse mesangial deposits of IgA are the hallmark of the disorder. Although the disease spontaneously remits in some children, progression to end-stage renal disease may occur. Occasionally, Goodpasture syndrome produces substantial urinary blood loss. Immunofluorescent staining of biopsy specimens reveals the characteristic antibodies to basement membrane lining the glomeruli. Blood loss into the urinary bladder can occur in association with infectious cystitis. Hematuria to the point of iron deficiency is extremely uncommon, however.

Patients with chronic intravascular hemolysis, such as those with paroxysmal nocturnal hemoglobinuria or arterial jet lesions from congenital or acquired heart disease with or without endovascular appliances, may also develop significant renal blood loss.

Pulmonary Blood Loss. Although pulmonary blood loss may be sufficiently severe to produce iron deficiency, it is distinctly rare. Idiopathic pulmonary hemosiderosis primarily affects children and young adolescents (reviewed by Specks[311]). Any child with iron deficiency and unexplained pulmonary disease should be evaluated for this potentially deadly disorder, which is characterized by slow but intractable hemorrhage into the bronchioles and alveoli. Iron deficiency anemia is a major part of the clinical picture of pulmonary hemosiderosis inasmuch as pulmonary macrophages are distinct from the normal iron-recycling circuit and iron trapped within these cells is effectively lost from the functional systemic pool. Consequently, a paradoxic situation evolves in which iron deficiency anemia develops in the presence of a surfeit of total body iron. Bronchoalveolar lavage reveals hemosiderin-laden macrophages that are characteristic of the disorder. Gastric aspiration, which is a less invasive procedure, may also reveal these cells due to swallowing of sputum. Chronic pulmonary infection with bronchiectasis, once considered to be a frequent cause of pulmonary hemorrhage, is now rare. Iron that accumulates in these cells induces the formation of toxic products, which leads to the activation of macrophages. These cells begin to damage the delicate lining of the bronchoalveolar tree and produce severe fibrosis. Oxygen exchanges poorly across the damaged alveolar surfaces, thereby lowering the efficiency of oxygen/carbon dioxide exchange. Late in the course of pulmonary hemosiderosis, the radiographic picture of the lungs is striking and frequently shows marked retraction and scarring.[312] The restrictive lung disease and substantial pulmonary arterial shunting across the lung may eventually be fatal.

Most often the cause of pulmonary hemosiderosis evades elucidation. In a number of patients, it occurs in conjunction with disorders of immune dysfunction, including celiac disease[313] and Goodpasture syndrome.[314,315] Treatment of the associated disorder can lead to remission of the pulmonary process, consistent with an immunologic mechanism of the lung injury.[316] Chloroquine treatment has been used with modest success in some patients.[317] Cyclophosphamide has produced responses in a number of patients.[318] A combination of prednisone and azathioprine has also been used.[319] Other immunosuppressive agents may prove to be even more effective as immunologic suppressers in the treatment of this condition, but the infrequency of the disorder means that a large, multicenter trial is needed to collect definitive treatment information. Although the prognosis was once believed to be very poor for all patients with idiopathic pulmonary hemosiderosis, more recent data suggest that such may not be the case.[316]

Menstrual Blood Loss. Blood loss associated with menstruation predisposes women to iron deficiency. In a sample of healthy, menstruating, nonpregnant Danish women 18 to 30 years of age not receiving iron supplementation, serum ferritin levels correlated inversely with the duration and intensity of menstrual bleeding.[320] Menorrhagia or dysfunctional uterine bleeding may lead to frank iron deficiency anemia. In many cases, dysfunctional uterine bleeding is due to anovulation, a common phenomenon in pubertal females. Progestational agents or oral contraceptives may ameliorate the dysfunctional uterine bleeding or menorrhagia. If this approach does not resolve the abnormal bleeding, other causes such as pelvic abnormalities or disorders of hemostasis, particularly von Willebrand disease, should be considered. Women with menorrhagia, especially menorrhagia present since menarche, have a high incidence of von Willebrand disease (13%), which in the general population is 1% to 2%.[321,322]

Consequences of Iron Deficiency

Although anemia is the most prominent manifestation of iron deficiency, there may be other clinically significant sequelae of iron deficiency, even in the absence of anemia. Organ and tissue dysfunction, including impaired immunity, decreased muscle performance and neurocognitive function, and poor weight gain, may occur with iron deficiency. Significant inroads in understanding some of these effects, particularly cognitive dysfunction in young children, have been made in the past few years.

Neurocognitive Effects. The association between iron deficiency anemia and impaired neurocognitive function is well established, and this association holds even when potential confounders such as psychosocial and environmental factors are taken into account. Infants and toddlers, who are undergoing critical neurocognitive development, may be at particular risk for such effects.[323]

Iron deficiency that has not yet progressed to anemia is also associated with impaired mental and motor functioning.[324,325] For example, when tested with the Bayley Scales of Infant Development, nonanemic iron-deficient infants had lower developmental scores than iron-sufficient infants did, and these abnormalities were detected in children as young as 9 to 12 months.[324] In addition, the degree of developmental deficits in infants may correlate with the level of iron deficiency.[325,326] Older populations of children, such as nonanemic iron-deficient preschoolers, have lower mental development scores,[327] and school-age children and adolescents have lower math and verbal scores than their iron-sufficient peers do.[327-330]

In some investigations, dietary iron supplementation has reversed the cognitive dysfunction.[324,325,328] For example, in the study of 9- to 12-month-old infants cited earlier, iron replacement increased Mental Development Index scores substantially in only 7 days.[324] Numerous other studies, however, failed to show improvement in depressed performance.[326,331-333] Lozoff and colleagues[334] have also demonstrated that these effects remain evident as long as 19 years later and that children of low socioeconomic status may be disproportionately affected. Older patients with iron deficiency may express a subjective state of cognitive impairment, likely reflecting central nervous system iron deficiency, that is rapidly reversed by treatment.

Iron deficiency may increase the risk for lead exposure through either pica or increased absorption. Concomitant lead toxicity can further hamper the psychological development of these children.[335] Information on the long-term effects of iron deficiency during infancy highlights the importance of early detection and intervention. Health care providers must therefore work actively to prevent and detect iron deficiency during infancy.

The mechanism by which iron deficiency impairs neurologic function is unknown. Iron deficiency could impair neurotransmitter mechanisms. It has been shown to decrease expression of dopamine receptors in the rat brain.[336] Iron deficiency may also interfere with myelination and alters myelin proteins and lipids in oligodendrocytes.[337] In addition, several enzymes in neural tissue require iron for normal function.[338] The cytochromes involved in energy production, for example, are predominantly heme proteins.

Pica. Pica, the compulsive consumption of nonnutritive substances, is a recurrent symptom in patients with iron deficiency. The precise pathophysiology of pica is unknown, but it is probably attributable to central nervous system iron deficiency. Patients often consume starch, ice, soil, foam, or clay. Both clay and starch can bind iron in the gastrointestinal tract and exacerbate the deficiency.[339,340] A dramatic example of the problems produced with clay consumption occurred in the 1950s in iron-deficient children along the border between Iran and Turkey.[341,342] These youngsters had other peculiar abnormalities, including massive hepatosplenomegaly, poor wound healing, and a bleeding diathesis. Presumably, the children initially had simple iron deficiency associated with pica, including geophagia. The soil contained compounds that bound both iron and zinc.[342] Secondary zinc deficiency was thought to cause the hepatomegaly and other unusual features.[341]

Epithelial Changes. Iron deficiency produces significant gastrointestinal tract abnormalities, reflecting the enormous proliferative capacity of this tissue. Angular stomatitis and glossitis with painful swelling of the tongue may develop. The flattened, atrophic, lingual papillae make the tongue smooth and shiny. A rare complication of iron deficiency is Plummer-Vinson syndrome, with the formation of a postcricoid esophageal web. Long-standing, severe iron deficiency affects the cells that generate the fingernails and produces koilonychia, or spooning. The nail substance is soft, so ordinary pressure on the fingertips, as occurs with writing, for instance, produces a concave deformity. Most of these abnormalities are now uncommon in industrialized nations and are particularly rare in children even given the relative frequency of iron deficiency.

Iron Deficiency Anemia. On physical examination, pallor, tachycardia, splenomegaly and a systolic murmur may be appreciated. As is true of all anemias, the anemia of iron deficiency impairs tissue oxygenation and produces the symptoms of pallor, weakness, fatigue, and lightheadedness. The morphologic features of the peripheral blood smear in patients with iron deficiency anemia vary greatly according to the severity and duration of the condition (Fig. 11-7). The earliest morphologic features of iron-deficient erythropoiesis in the peripheral blood are subtle variations in red blood cell size and the degree of hemoglobinization, with occasional smaller, less well hemoglobinized cells recognizable. These parameters are reflected by changes in the red cell distribution width (RDW) and the hemoglobin distribution width (HDW) and are usually present before overt hypochromia and

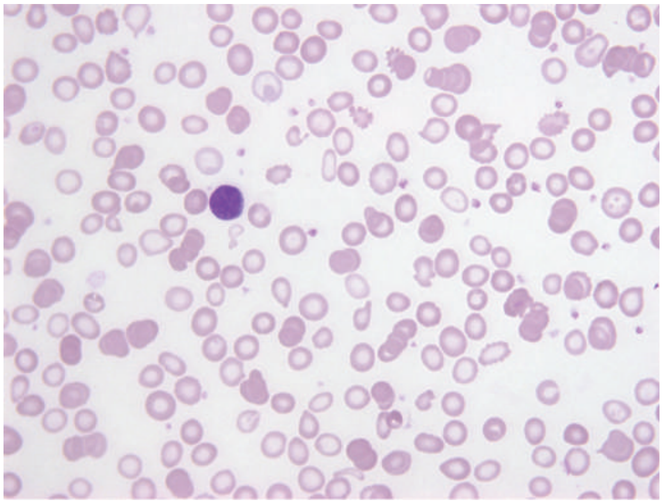

Figure 11-7 Peripheral blood smear in iron deficiency. Note the small, pale (microcytic, hypochromic) red blood cells with variable sizes and shapes (anisopoikilocytosis). Occasional target cells with central hemoglobin pooling as well as several somewhat elongated hypochromic microcytes (pencil cells) are present.

microcytosis are seen. Indeed, at this point, the hemoglobin and the mean cell volume (MCV) may be in the normal range. As the severity and duration of iron-deficient erythropoiesis increase, so do the extent of morphologic changes, with increasing variation in cell size (anisocytosis) and hypochromia and distinctive misshapen hypochromic microcytes with irregular, often angulated borders present (poikilocytes). The plasma membranes of iron-deficient red cells are abnormally stiff, and such cells are more prone to hemolysis.[343] This rigidity may contribute to poikilocytic changes, seen particularly with severe iron deficiency. Small, stiff, misshapen cells are cleared by the reticuloendothelial system, thereby further contributing to low-grade hemolysis. The cause of this alteration in membrane fluidity is unknown. Very thin, elongated hypochromic cells, so-called pencil cells, are said to be characteristic of iron deficiency. Occasional target cells, in which hemoglobin pools in the center of the erythrocyte, may be seen, but these cells, as well as polychromasia, indicative of a reticulocytosis, are not as prevalent as in β-thalassemia. Basophilic stippling, nucleated red blood cells, or nuclear remnants (i.e., Howell-Jolly bodies) are generally not present, distinguishing severe iron deficiency from thalassemias or hemoglobinopathies. β-thalassemia trait (see Chapter 21) also produces microcytic cells and borderline anemia and is sometimes confused with early iron deficiency. Iron deficiency, however, alters red cell size unevenly, resulting in a high RDW, which is typically normal in β-thalassemia trait.[344] Other common features of β-thalassemia trait are rare cells with basophilic stippling and target cells, which are generally not present in the earliest phases of iron deficiency. These characteristics are not sufficiently distinctive to be diagnostically definitive, however, and any suspicion should be confirmed with more objective tests such as a hemoglobin electrophoresis. Importantly, iron deficiency may lead to an elevated hemoglobin A2, confounding the interpretation of hemoglobin electrophoresis results. Given the not uncommon coexistence of iron deficiency and β-thalassemia trait, any abnormal hemoglobin electrophoresis should be interpreted in the context of iron studies (see below) and repeated after iron supplementation in the iron-deficient patient.

Thrombocytosis with platelet counts in the range of 500,000 to 700,000 cells/fL occurs frequently in iron-deficient patients. Megakaryocytes and normoblasts are derived from a common committed progenitor cell, the colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte (CFU-GEMM). Thrombopoietin, the molecule that stimulates the growth of megakaryocytes and the production of platelets, is homologous to erythropoietin (see Chapter 6). The high levels of erythropoietin produced by iron deficiency anemia conceivably could cross-react with megakaryocyte thrombopoietin receptors and modestly raise the platelet count. However, this hypothesis has not been proved experimentally.

Bone marrow examinations are no longer routinely used to assess iron stores. However, when they are performed, in severe cases, late erythroblasts often have ruffled or frayed edges, not unlike other hypochromic anemias. Iron staining is best performed on aspirate smears rather than biopsies, as decalcification can leach iron out of the sample, resulting in false-negative results, and the cytologic preservation is typically inadequate to resolve minute, intraerythroid iron granules (sideroblasts, see below) indicative of erythroid iron sufficiency. Iron-stained marrow particles should have readily identifiable cells with coarse iron positivity, representing macrophages with abundant ferritin and hemosiderin storage iron. If particles are absent, careful microscopic examination of normal, iron-replete bone marrows under oil immersion should demonstrate up to 30% to 40% of the erythroid precursors with several fine, peripherally placed iron deposits that represent iron in cytosolic ferritin. Such cells are termed *sideroblasts*, are entirely normal, and are absent or decreased in iron deficiency. In the anemia of inflammation, where there is a defect in iron recycling, macrophage iron stores may be present but intraerythroblast iron will be decreased or absent (see below).

Diagnosis of Iron Deficiency

Because they are inexpensive and widely available, hematologic markers are frequently used to assess iron status. A hemoglobin content less than the fifth percentile in a reference population is often used to define anemia. Changes in erythrocyte parameters accompanying iron deficiency anemia include a decrease in MCV, reflecting microcytosis, and an increase in RDW, reflecting anisocytosis, as described earlier. Because these parameters represent averages of the entire red blood cell population, iron deficiency must be present for some time before it deviates from these measures.

The American Academy of Pediatrics and the U.S. Centers for Disease Control and Prevention recommend the use of hemoglobin to screen children at risk for iron deficiency. Because only the later stages of iron deficiency result in anemia, relying on hemoglobin (or hematocrit) to screen for iron deficiency misses many children who are, in fact, iron deficient and in whom adverse consequences, such as potentially irreversible neurocognitive impairment, may have already begun to occur. For example, based on NHANES data, a hemoglobin concentration of less than 11 g/dL has a sensitivity of 30% for detecting iron deficiency, as defined by ferritin, erythrocyte protoporphyrin, and transferrin saturation (see below).[345] That adverse consequences of iron deficiency may occur in the absence of anemia highlights the importance of diagnostic approaches that detect iron deficiency early, without relying on hematologic indicators that are altered only after iron deficiency has progressed.

Serum or plasma biochemical parameters based on iron metabolism are often used to diagnose iron deficiency. The tests that are commonly employed, as well as their physiologic relevance and confounding variables, are listed in Table 11-1. Plasma iron concentrations, largely reflecting the iron recycled from effete red blood cells, fall as iron is depleted, but they are also affected by diurnal variation and dietary intake. The availability of plasma iron-binding sites, or TIBC, increases as iron stores fall. Serum iron concentration divided by TIBC yields the transferrin saturation, which is expressed as a percentage of transferrin iron-binding sites occupied by

TABLE 11-1 Common Clinical Laboratory Tests to Assess Iron Status[*]

Test	What It Indicates	Result in Iron Deficiency	Result in Iron Overload	Confounding Conditions
Iron	Iron recycling/usage, stores (indirect)	↓	↑-↑↑	↓ in inflammation
Total iron-binding concentration (TIBC)	Serum/plasma transferrin	↑	Normal	↓ in inflammation
Transferrin saturation	% plasma iron-binding sites on transferrin that are occupied	↓-↓↓	↑-↑↑	↓ in inflammation
Free or zinc protoporphyrin	Functional mitochondrial iron status	↑	Normal	↑ in reticulocytosis
Soluble transferrin receptor (sTfR)	Erythropoietic mass	↑	Normal	Ineffective erythropoiesis
Ferritin	Iron stores (indirect)	↓-↓↓	↑-↑↑	↑ in inflammation
Bone marrow iron	Macrophage iron stores/retention, red blood cell iron uptake	↓	Normal to ↑	↑ in inflammation
Liver iron	Iron stores	↓-↓↓	↑-↑↑	Secondarily increased in cirrhosis
Hepcidin[†]	Hepatocyte iron	↓-↓↓	↑-↑↑	↑ in inflammation

[*] All measures are in serum or plasma unless otherwise indicated.
[†] Hepcidin is not yet routinely available as a clinical test.

iron. A transferrin saturation of less than 10% is a stringent definition of iron deficiency that is often employed as the "gold standard" against which other tests are judged. However, erythropoiesis is to some extent iron restricted at a transferrin saturation of 15% or less. Serum ferritin is a glycosylated form of the intracellular iron storage protein L-ferritin that is incapable of binding iron. The precise ontogeny and cells of origin of this circulating form of the protein are uncertain. Nevertheless, the serum ferritin is a good biomarker of total body iron stores and is roughly linearly related to this parameter over a wide range—from iron deficiency to moderate iron overload. A low serum ferritin level is a very specific indicator of iron deficiency, but ferritin is an acute-phase reactant and is elevated in chronic inflammatory states, independent of body iron status, thus reducing the sensitivity of the test. Ferritin has in fact been shown to be a poor indicator of iron deficiency in the pediatric population.[272] Whereas ferritin is a "positive" acute-phase reactant and may lead to an overestimate of iron stores in the setting of inflammation, serum iron and TIBC are "negative" acute-phase reactants and are reduced in this context.

Because of the limitations of both hematologic and biochemical tests, novel methods of diagnosing iron deficiency have been sought. Measures of red blood cell protoporphyrin IX, particularly zinc protoporphyrin (ZPP), assess the functional availability of iron to the erythrocyte mitochondrion, where iron is incorporated into protoporphyrin IX by ferrochelatase to form heme. In the context of mitochondrial iron insufficiency, zinc, an alternative ferrochelatase substrate, is inserted into the protoporphyrin ring. Measurement of the absolute level of red blood cell ZPP or, more specifically, the ratio of ZPP to iron protoporphyrin IX (i.e., heme), which is increased in iron deficiency, therefore provides an assessment of delivery of iron to erythroid mitochondria for heme synthesis.

sTfR is a truncated form of the transferrin receptor that is cleaved from reticulocytes and erythroid cells and circulates in plasma largely bound to transferrin. sTfR is increased in iron deficiency but is also increased in other anemias characterized by ineffective erythropoiesis (e.g., thalassemia). Though not uniformly available in all clinical laboratories, it may be a particularly important adjunct in distinguishing iron deficiency anemia from the anemia of inflammation, in which it is not increased.[346-348]

The cellular hemoglobin of the reticulocyte (CHr) is another test available only in selected laboratories because it is unique to instruments manufactured by Bayer (Tarrytown, NY). CHr has been evaluated prospectively as a means of routinely screening infants and toddlers.[273] In this setting, a CHr cutoff of 27.5 pg had 83% sensitivity and 72% specificity, whereas a hemoglobin concentration of less than 11 g/dL was a poor predictor of iron deficiency, with only 26% sensitivity. CHr has also been used to accurately assess the iron status of potential adult blood donors.[349] A summary of the relative sensitivity and specificity and approximate cost of each of the tests commonly employed to screen for iron deficiency is shown in Table 11-2.

Although commercial tests for urinary or plasma hepcidin are not yet currently in clinical use, measurement of this analyte may well have a role in assessing iron status, whether it be deficiency or overload, in the future. This will certainly be the case if algorithms for determining if the hepcidin is appropriate, or inappropriately high or low, for the clinical context, permitting some insight into the pathophysiology of the disorder under investigation. However it is ultimately implemented, analysis of hepcidin levels will, similar to the serum ferritin, be

TABLE 11-2 Sensitivity, Specificity, and Cost of Common Tests to Screen for Iron Deficiency

Method	Age	Cost	Sensitivity	Specificity	Reference
Transferrin saturation (<10%)	any	≈\$85	100%	100%	"Gold standard" defined as 100% sensitive and specific
Hb (<11 g/dL)	9-12 months	≈\$30	26%	95%	273
Hb (<10.7 g/dL)	9-12 months	≈\$30	67%	87%	623
MCV (<71 fL)	9-12 months	≈\$30	86%	83%	623
CHr (<27.5 pg)	9-12 months	≈\$50	83%	72%	273
Spun Hct (<33%)	9-36 months	≈\$15	16%	92%	624
Ferritin (<10 µg/L)	4-15 months	≈\$65	71%	57%	346
Ferritin (<10.9 µg/L)	9-12 months	≈\$65	83%	80%	625
ZPP (>50 nmol/mol heme)	9-36 months	≈\$150	81%	88%	624
FEP (>2.12 µmol/L RBC)	4-15 months	≈\$150	82%	57%	346
sTfR (>13.5 mg/L)	4-15 months	≈\$90	31%	95%	346

confounded by concomitant inflammation, or, like sTfR, ineffective hematopoiesis.

Treatment of Iron Deficiency

The most important steps in the evaluation and treatment of iron deficiency are determining the cause and correcting the abnormality. Malignant disease of the gastrointestinal tract, the most worrisome cause in adults with iron deficiency, is vanishingly rare in children. Whereas in children, growth spurts, poor dietary patterns, menstrual losses, and non-malignant causes of gastrointestinal bleeding are more often the cause of iron deficiency. After initial diagnostic investigations, oral iron supplementation usually replaces stores most efficiently.

Oral Supplementation. Iron salts offer inexpensive, effective therapy for iron deficiency. Although ferrous sulfate is most often recommended, patients frequently complain of gastrointestinal discomfort, constipation, and bloating, as well as stool discoloration, thus making its use unacceptable to many. Interestingly, in a randomized, controlled trial comparing 3 mg/kg/day of ferrous sulfate drops with placebo in 278, 12-month-old infants, there was no difference in the frequency of vomiting, diarrhea, or fussiness, and infants in the placebo group had a higher incidence of constipation (95% vs. 1%).[350] Iron is frequently provided to children at a dose of 3 mg/kg/day divided into three-times-a-day dosing. Single-dose daily regimens, however, are tolerated as well as three-times-a-day regimens.[351] Administration of iron on an empty stomach at night will lessen the gastrointestinal difficulties. The decreased gastrointestinal motility of sleep will also enhance absorption.

The absorptive capacity of the normal duodenum for iron is essentially saturated with about 25 mg of elemental iron in ionic form. Ferrous gluconate, which is roughly equivalent in cost, contains about 50 mg of elemental iron per tablet. This form of replacement may produce fewer problems than ferrous sulfate and is excellent as the initial treatment of iron deficiency. Ascorbic acid supplementation enhances iron absorption, although it has a relatively minor effect in individuals ingesting normal, balanced diets.[352] Combination tablets containing iron salts and ascorbic acid are significantly more expensive than separate tablets for each. Even with faithful use of oral iron, adequate replacement of body stores in patients with moderate iron deficiency anemia requires several months. With ongoing blood loss, replacement of stores with oral iron becomes very difficult.

Polysaccharide/iron complexes differ from iron salts. Polar oxygen groups in the sugars form coordination complexes with iron atoms. The well-hydrated microspheres of polysaccharide iron remain in solution over a wide range of pH values. Most patients tolerate this form of iron better than the iron salts, even though the 150 mg of elemental iron per tablet is substantially more than that provided by iron salts.

Iron supplements must be stored in a childproof manner. Unintentional iron poisoning from iron supplements is a leading cause of injury related to poisoning in young children and frequently occurs when children obtain improperly stored iron.[353]

Box 11-3 lists potential causes of a poor response to oral iron supplementation. A variety of barriers, including treatment-associated factors and system-wide barriers, contribute to the shortcomings in iron deficiency screening and correction that have been documented.[354]

Parenteral Iron Replacement. Parenteral iron is now available in the United States in four intravenous forms: iron dextran, iron gluconate, iron sucrose,[355] and iron oxide coated with polyglucose sorbitol carboxymethylether.[356-360] Only some of these products are approved specifically for use in the pediatric population. Intravenous iron therapy is indicated when (1) oral iron is poorly tolerated; (2) rapid replacement of iron stores is needed; (3) gastrointestinal iron absorption is compromised; or

Box 11-3 Causes of Poor Response to Oral Iron Supplementation

- Noncompliance
- Ongoing blood loss
- Insufficient duration of therapy
- High gastric pH
  - Antacids
  - Histamine$_2$ blockers
  - Gastric proton pump inhibitors
- Inhibitors of iron absorption or utilization
  - Lead
  - Aluminum intoxication (hemodialysis patients)
  - Chronic inflammation
  - Neoplasia
- Incorrect diagnosis
  - Thalassemia disorder
  - Sideroblastic anemia
  - Anemia of chronic inflammation
- Genetic disorder of iron absorption or utilization (e.g., iron-refractory, iron deficiency anemia [IRIDA])

(4) erythropoietin therapy is necessary, particularly in renal dialysis patients. Iron dextran can also be administered by intramuscular injection, but this route is discouraged because it can be painful and leakage into subcutaneous tissue produces long-standing skin discoloration. A "Z-track" injection into the muscle minimizes the chance of subcutaneous leakage. The suboptimal muscle mass frequently associated with nutritional deficiency further complicates this mode of replacement. Intravenous infusion circumvents these problems altogether. With either route of administration, a small test dose should be given and the patient observed by a physician for 30 minutes to rule out an anaphylactic reaction to the medication. Such reactions do occur but are infrequent. The newer iron sucrose and iron gluconate preparations are believed to be less likely to cause complications, but there is less accumulated experience with these preparations, and many practitioners still use iron dextran routinely.

Ten percent to 15% of patients experience transient mild to moderate arthralgias the day after intramuscular or intravenous administration of iron dextran. Acetaminophen usually relieves the discomfort effectively. Iron dextran is generally avoided in patients with rheumatoid arthritis because it may provoke painful flares of their disease.[12] The symptoms may result from release of inflammatory cytokines such as interleukin-1 and tumor necrosis factor. Iron dextran is cleared from the circulation by macrophages, which are probably activated to release proinflammatory peptides.

In uncomplicated cases of iron deficiency, intravenous replacement may produce subjective improvement in symptoms within a few days. Peak reticulocytosis occurs after about 10 days, and complete correction of the anemia takes 4 to 6 weeks, although the hematocrit rises sufficiently in 1 or 2 weeks to provide symptomatic relief for most patients.[352] CHr is a very sensitive measure of response.[361] Brugnara and colleagues[361] have demonstrated that a rise in CHr is appreciated within 2 to 4 days of the administration of intravenous iron.

Refractory bleeding that cannot be prevented, as occurs, for example, with hereditary hemorrhagic telangiectasia, presents a management problem. Oral iron supplementation often fails to keep pace with losses. Blood transfusions replace red cells in the short term and iron in the long term, but infection and alloimmunization make such therapy unacceptable for many patients. Intermittent iron replacement with infusions of intravenous iron is the most reasonable alternative. Replacements should occur over short intervals two or three times a year, with the aim of repleting body stores. A simple formula can be used to determine the replacement dose of iron dextran:

$$\begin{aligned}\text{Dose (mL)} = {} & 0.0442 \times (\text{Desired Hb} - \text{Observed Hb}) \\ & \times \text{Lean body weight} \\ & + (0.26 \times \text{Lean body weight})\end{aligned}$$

Alternatively, there is a calculator provided on the Internet at infed.com/calcltor.htm. The maximum adult dose of iron dextran is 14 mL.

Over many years this treatment can produce massive deposition of hemosiderin (from iron dextran) in macrophages, the liver, and the pancreas despite the fact that plasma transferrin is iron deficient because of increased iron delivery to erythroid precursors. This supports the concept that tissue iron content is unimportant for erythropoiesis and that erythropoiesis relies exclusively on iron from transferrin.[94,134]

Iron Replacement in Infants. Because the fetus accumulates iron at the mother's expense in the third trimester of pregnancy, full-term infants are born with adequate iron stores to last approximately 6 months. Preterm infants are at greater risk for iron deficiency, with their stores depleted by 3 to 4 months of age.

Human breast milk initially contains relatively high amounts of iron, but the level decreases, independent of maternal iron status, to approximately 0.3 mg/L after 5 months of lactation (reviewed by Griffin and Abrams[362]). The iron is present in several forms: in casein, in whey, in fat, and to a small extent, in the abundant protein lactoferrin. The rate of absorption of iron from human milk has been estimated to be 20% to 50%, which is adequate early in life when iron stores are still high but inadequate to meet an older infant's needs. Based on all available information, the Committee on Nutrition of the American Academy of Pediatrics has recommended the following[279]:

1. Breast milk should be provided for at least 5 to 6 months when feasible. During that period, young infants can mobilize iron from their large stores. Iron supplementation of 1 mg/kg/day should be provided to infants who are exclusively fed breast milk beyond 6 months of age.
2. Infants who are not breastfed should be nourished with an iron-supplemented formula (at least 12 mg/L) until the end of the first year of life.
3. Iron-enriched cereals should be among the first foods introduced with a solid diet.
4. Cow's milk should be avoided during the first year because it contains substances that chelate iron and

it sometimes induces occult gastrointestinal hemorrhage in young infants.

Maternal Iron Stores and Effects on the Fetus

When the mother is iron deficient, the placenta is concerned only with the welfare of the fetus and will continue to remove iron from the mother to support fetal development, even at the cost of negative maternal iron balance. For years, investigators debated the effect of maternal iron deficiency on the fetus. Early findings by Cook and colleagues[363] indicated that the iron storage status of the mother does not affect the infant's iron status as measured by ferritin. The controversy was fueled by the indirect and imprecise assays of neonatal iron status, such as the cord blood ferritin level or transferrin saturation. These parameters in cord blood are subject to all the vicissitudes that affect their values in later life. Accurate determination of neonatal iron status was difficult, if not impossible. The one point on which nearly universal agreement existed was that neonatal anemia secondary to maternal iron deficiency is rare.

It is likely that in fact maternal iron status over a wide range of values does affect the iron stores of the neonate. The most compelling data have come from a study of women who underwent elective abortions.[363,364] The iron status of the mothers was determined from transferrin saturation, plasma ferritin levels, and hemoglobin values. This information was correlated with the iron status of the fetuses, which was determined by atomic absorption spectroscopy of the complete abortus. This procedure determined the absolute fetal iron content. Fetal iron stores varied linearly with maternal hemoglobin, which ranged between 6 g/dL (severe iron deficiency) and 13 g/dL (adequate, though possibly low, iron stores).

Fetal iron stores, in turn, may influence neonatal outcomes. Maternal iron deficiency before midpregnancy is associated with an increased risk for preterm delivery. Maternal anemia detected during the last trimester of pregnancy is not associated with an increased risk for preterm birth. This anemia probably reflects the expansion of maternal plasma volume rather than actual maternal iron stores.

Neonatal iron stores are also influenced by other maternal factors apart from iron stores. Maternal diabetes is associated with decreased fetal stores, as evidenced by lower cord blood ferritin and an increased demand for iron reflected by higher soluble transferrin receptor levels.[365] This may be due to neonatal polycythemia and increased erythropoietic drive associated with maternal diabetes. Similarly, maternal smoking is also associated with increased cord hemoglobin and decreased iron stores.[366]

The infant's gestational age is related to the development of adequate iron stores, as described earlier. The timing of umbilical cord clamping at birth may also affect neonatal iron stores. A randomized, controlled trial of delayed clamping (2 minutes after delivery) versus usual clamping found that infants in the group with delayed umbilical cord clamping had higher ferritin and total body iron stores at 6 months of age.[367] The effect of delayed clamping was particularly pronounced in infants otherwise at risk for iron deficiency, such as infants not receiving iron-fortified milk or formula, infants of mothers with low ferritin levels at birth, and lower–birth-weight infants.

Iron supplementation for pregnant women during the first 28 weeks is associated with a higher mean birth weight and a lower incidence of low–birth-weight infants, but not maternal anemia or higher preterm delivery rates.[368] Consequently, at this time there is insufficient evidence to support or reject the routine practice of prophylactic iron supplementation during pregnancy as opposed to supplementing iron-deficient pregnant women or those at risk for iron deficiency.

Iron Overload

The Evolutionary Advantage of Iron Overload

The fact that multiple mutations in diverse populations all lead to iron overload (see later) raises the possibility that these conditions once conferred a selective advantage. As previously noted, iron deficiency is the most common nutritional cause of anemia in the world. Anemia was probably a survival or reproductive disadvantage earlier in human history. A genetic change that increased the efficiency of iron absorption may therefore have been an advantage. A person who survived into the third decade would have reproduced and passed genes to the next generation, including those that increase iron absorption. Survival into the fifth decade, when severe iron overload begins to produce problems, was uncommon until recently. However, a problem develops with this tidy theory when the inhabitants of Asia are considered. The incidence of iron overload is reportedly quite low in this region of the world, the home of most of the earth's population.

Hereditary Hemochromatosis

Hereditary hemochromatosis is a condition that originates from a genetic predisposition to iron overload as a result of mutations in one of several genes involved in iron metabolism (see Fig. 11-6). It is caused by an alteration in the iron absorption mechanism that fractionally increases the uptake of dietary iron.[369,370] Although the rate and extent of iron loading vary widely among patients, dangerous levels of tissue iron develop in many people by middle age. Iron deposits in cells of the liver, heart, and endocrine tissues. It promotes oxidative cell damage, which leads to fibrosis and, when unrecognized, to the classic manifestations of "bronze diabetes," including liver dysfunction, increased melanization of the epidermis, and pancreatic insufficiency.[371] Because erythropoiesis is normal, iron can be removed through phlebotomies performed regularly. If untreated, hemochromatosis may be a lethal disease and result in death from cirrhotic liver failure or, less often, from cardiomyopathy.

Pediatricians are often asked to evaluate children who have close relatives with hemochromatosis. This is a complicated task because iron loading occurs gradually over a period of many years and may not be apparent before adulthood. Although the genes responsible for most forms of hemochromatosis have been identified, at this

time commercial laboratories test for only one form of the disease. However, this situation is likely to change over the next few years and simplify presymptomatic diagnosis. Until then, assessment should take into account the family history, serum transferrin saturation, serum ferritin levels, and, if indicated, quantitative liver iron determined by analysis of a biopsy sample (Fig. 11-8).

In the United States, Canada, Australia, and the northwestern part of Europe, most patients with hemochromatosis are homozygous for a unique missense mutation designated C282Y (for cysteine 282 to tyrosine) in the gene encoding HFE, a protein that resembles class I major histocompatibility (MHC) molecules.[372] The *HFE* gene lies on chromosome 6p, near the HLA-A locus. It was discovered through a positional cloning approach that took advantage of the fact that patients with the C282Y mutation are descended from a common ancestor (i.e., founder effect) who probably lived in a Celtic population in the British Isles 60 to 70 generations ago.[373]

Like class I MHC proteins, HFE forms a heterodimer with β2-microglobulin and is expressed on the cell surface. However, unlike other family members, HFE cannot bind a small peptide. Its structure, as determined by x-ray crystallography, does not allow enough space within the groove that is involved in peptide binding by MHC class I molecules.[374] Some insight into the function of HFE was gained from observations that it forms a high-affinity complex with the transferrin receptor.[374] HFE binds to a site that overlaps the binding site for diferric transferrin, which results in competition between HFE and transferrin for occupancy of the transferrin receptor.[375] Studies in transfected cells overexpressing HFE indicate that the HFE–transferrin receptor association alters cellular iron uptake. However, the effect of HFE on iron homeostasis is not directly attributable to its effect on cellular iron uptake. As discussed later, we now know that HFE and several other forms of hemochromatosis result from aberrant expression of the iron regulatory hormone hepcidin.

In patients with HFE hemochromatosis, serum transferrin becomes saturated with iron before clinical signs appear. The increased serum iron is deposited in parenchymal cells of the liver, heart, pancreas, and other tissues. In knockout mice lacking murine Hfe, an iron overload disorder develops that closely resembles human hemochromatosis.[376,377] The mutant allele for HLA-linked hemochromatosis is prevalent in the United States. Studying a cross section of the American population, Steinberg and colleagues[378] found that 9.5% of non-Hispanic whites, 2% of non-Hispanic blacks, and approximately 5% of the population overall were C282Y carriers. Testing for the HFE C282Y mutation allows identification of patients in whom clinical hemochromatosis may develop. Heterozygotes rarely have clinically significant iron overload, but homozygotes are at risk. Published data give conflicting estimates of the proportion of patients homozygous for C282Y in whom complications of the disease will develop; such estimates range from less than 1% to greater than 20%. It is clear, however, that some individuals have severe iron loading as young adults whereas others may never manifest signs or symptoms of hemochromatosis. There must be both environmental and genetic modifiers that affect the extent of iron loading. Current efforts are aimed at defining these modifiers to aid in predicting in which genetically at-risk individuals clinically significant iron overload will develop.

Other polymorphisms and potential mutations have been described in the HFE coding sequence. One of these polymorphisms, H63D (histidine 63 to aspartic acid), is prevalent throughout the world and found in as many as a quarter of asymptomatic patients, often in combination with the C282Y allele. Although clinical laboratories currently test for and report the H63D polymorphism, most patients with one or two copies of the H63D allele are probably not at risk for iron loading. Other polymorphisms associated with altered amino acids or altered mRNA splicing have also been reported (reviewed by Camaschella and coworkers[379]). Some of these polymorphisms do appear to be associated with iron overload, but most clinical laboratories do not test for them.

Since the identification of HFE, it has become clear that there are at least four other types of hemochromatosis, and that most forms are associated with loss of a protein that regulates hepcidin gene transcription in the hepatocyte through a bone morphogenetic protein/sons of mothers against decapentaplegic (BMP/SMAD)–dependent signaling cascade that is modified by TMPRSS6 and the interaction of the HFE protein with TRFC (see Fig. 11-6). A disorder that may be clinically indistinguishable from HFE-associated hemochromatosis results from homozygosity for mutations in the gene encoding transferrin receptor 2 (TFR2).[380] TFR2 is highly homologous to the transferrin receptor, particularly in its extracellular domain, but it binds transferrin with much lower affinity.[381,382] It is primarily expressed in the liver and in erythroid cells. Its function remains incompletely understood, but, similar to the transferrin receptor, TFR2 forms a protein complex with HFE, which is believed to be involved in regulation of hepcidin expression.[383]

Two other types of hemochromatosis are easier to distinguish from HFE-associated hemochromatosis. Juvenile hemochromatosis, also called type 2 hemochromatosis, is a more severe disorder with accelerated iron loading that typically leads to death by the third decade.[384] Patients have iron deposition in the same pattern as that seen in those with HFE-associated hemochromatosis, but the rapid accumulation of metal leads to a different clinical picture dominated by cardiac disease and endocrine dysfunction. Patients are often identified when they fail to enter puberty or develop secondary amenorrhea. If these patients are recognized before end-stage organ disease develops, they can be treated by aggressive phlebotomy. Juvenile hemochromatosis is inherited in an autosomal recessive pattern and is caused by mutations in *HAMP*, the gene encoding hepcidin,[385] or in an unrelated gene encoding hemojuvelin (*HJV*, also called *HFE2*, *RGMC*).[386] Hemojuvelin is a cell surface protein that acts as a bone morphogenetic protein (BMP) coreceptor to stimulate hepcidin expression, presumably in response to BMP signals.[387] BMP6 appears to be the primary, but not the only, BMP ligand, relevant to this iron-dependent signal transduction pathway. Targeted disruption of the murine hepcidin or hemojuvelin genes results in a phenotype very similar to human juvenile hemochromatosis, with a complete or near absence of hepcidin mRNA expression.[388-391]

Although all of the forms of hemochromatosis discussed thus far (caused by mutations in *HFE*, *TFR2*, *HAMP*, and *HJV*) are associated with inappropriately low hepcidin production, particularly when compared with the degree of iron stores, there is one hemochromatosis disorder that is not. A subset of patients carrying mutations in *SLC40A1*, the gene encoding ferroportin, has autosomal dominant hemochromatosis that is otherwise clinically similar to other forms of the disease.[392-394] Apparently, these mutations render ferroportin resistant to hepcidin regulation; these individuals have appropriately high levels of hepcidin. A second class of ferroportin mutations cause a distinct autosomal dominant disorder characterized by macrophage iron loading, an early rise in serum ferritin levels, comparatively less saturation of transferrin with iron, and no major increase in total body iron stores.[247,395,396] These alleles appear to be mutations leading to partial loss of function and particularly impair macrophage iron recycling. Both forms of "ferroportin disease" are autosomal dominant because functional ferroportin exists in cells as a dimer and mutation of one subunit in a dimer is sufficient to alter for transport or hepcidin responsiveness.[397]

African Iron Overload Syndrome

During the 1960s, several groups of investigators reported that iron overload occurred at a very high rate among sub-Saharan Africans.[398-401] Many patients had massive iron stores approaching or exceeding those seen in individuals with hemochromatosis. Some indigenous inhabitants of the region prepared alcoholic beverages in nongalvanized steel drums, thus raising the possibility that iron overload resulted from the high iron content of these beverages. Iron loading was thought to be exacerbated by an increase in gastrointestinal iron absorption induced by alcohol. The term *Bantu siderosis* was coined to describe the condition.[401]

Later reports suggested that African iron overload syndrome was not simply the result of increased intake.[402-404] In only a fraction of the group who drank the beverage did iron overload develop. In fact, a more extensive study showed that similar degrees of iron overload occurred in people who consumed little, if any, of this brew. Although the pattern of inheritance has not been definitively worked out, the disorder may be autosomal codominant, with obligate heterozygotes expressing an intermediate level of iron loading. African iron overload syndrome is not associated with *HFE* mutations.[405]

In contrast to other forms of hereditary hemochromatosis, in which the iron is almost entirely confined to parenchymal cells, reticuloendothelial macrophages display massive iron deposition in the African variety of iron overload.[398] A common missense mutation in ferroportin, Q248H, has been implicated as a possible genetic factor.[406,407] However, the ultimate clinical consequences of iron overload are similar to those seen in all other forms of hemochromatosis, irrespective of the cause of the accumulation. African iron overload syndrome is not confined to any ethnic group, although it appears to be restricted to the inhabitants of sub-Saharan Africa. In some areas, the incidence may be as high as 10%, which makes it one of the most common, clinically significant iron disorders in any population.

An important, unanswered question is whether mutated genes causing this syndrome are found in people of African descent elsewhere in the world. No comprehensive study of iron overload has been performed in African Americans, but preliminary data suggest that a substantial portion of this population may be at risk.[408,409] There has not yet been an exhaustive examination of hemochromatosis disease genes in this group.

Neonatal Hemochromatosis

Neonatal hemochromatosis (NH) is a rare condition characterized by neonatal liver failure associated with systemic iron overload, parenchymal iron deposition, thrombocytopenia, and coagulopathy in the absence of evidence of any known causative agent or condition, including Down syndrome, metabolic liver disease (e.g., tyrosinemia, galactosemia), congenital infection (e.g., herpesviruses), or congenital anemia (e.g., α-thalassemia, hydrops fetalis secondary to ABO/Rh incompatibility) (reviewed elsewhere[410-413]). In addition to fetal diseases, NH has been associated with maternal autoimmune disorders, including lupus erythematosus and Sjögren syndrome. Although iron chelation and antioxidant cocktails have been studied and occasionally have led to some clinical improvement, the outcome in NH is nearly always fatal in the absence of prompt hepatic transplantation.[414-416] The rare individuals who have survived without transplantation have recovered full organ function,[417,418] and the disease usually does not recur in those who have undergone transplantation successfully, thus suggesting that the hepatic insult is developmental or transient in nature.

Mutations in several of the "adult" hemochromatosis genes have not been identified in NH patients, and there is substantial evidence of a nonmendelian or otherwise unconventional hereditary predisposition to NH.[411,412,419] Specifically, the possibility of mitochondrial inheritance or inheritance of a maternally imprinted gene has been raised by the discovery of several kindreds in which women have borne affected children fathered by different men. However, neither of these types of inheritance can account for the tendency for a mother's first pregnancy to be spared or mildly affected by the disorder whereas subsequent pregnancies have a greater than 50% risk for the development of clinically overt NH. These latter observations, in particular, have spawned the current leading hypothesis that NH is the consequence of prenatal alloimmune liver injury.[413,420] In this model, which parallels the paradigm of neonatal alloimmune thrombocytopenia (see Chapter 34), the mother is sensitized to a fetal antigen during a first pregnancy and subsequent pregnancies provoke an amnestic immune response that results in a severe clinical phenotype. What the antigen might be or how it perturbs iron metabolism is unknown. Nonetheless, a recent clinical trial demonstrated that clinically significant liver disease can be avoided in the vast majority of at-risk fetuses by treating the expectant mother with intravenous immunoglobulin beginning in the early second trimester of gestation, thus further substantiating the alloimmune hypothesis.[420]

Iron Overload Caused by Erythroid Hyperplasia and Ineffective Erythropoiesis

The connection between hematopoiesis and iron absorption is most strikingly apparent in patients with ineffective erythropoiesis. With disorders such as nontransfused β+-thalassemia (thalassemia intermedia), X-linked sideroblastic anemia, and congenital dyserythropoietic anemias, the fractional absorption of ingested iron is increased. Patients with these disorders can manifest iron overload without transfusion.[421]

The mechanism by which bone marrow activity modulates gastrointestinal iron absorption is only partially understood. A soluble factor appears to be released that depresses hepcidin production.[422] Recently, it was reported that GDF15, a member of the transforming growth factor β (TGFβ) superfamily, is induced in patients with thalassemia and that GDF15 suppresses expression of hepcidin by human hepatocytes.[53] Another TGFβ superfamily member, twisted gastrulation 1 (TWSG1) is reported to have similar properties.[54] It is, however, highly likely that there are other soluble factors that contribute to the "erythroid regulator."

In humans, depressed hepcidin levels and, consequently, robust absorption of iron from the gastrointestinal tract are associated most often with ineffective erythropoiesis.[58] Some patients with pyruvate kinase deficiency, a condition frequently associated with reticulocyte counts as high as 70%, manifest iron overload without transfusion. Hemolytic anemias with effective erythropoiesis rarely lead to iron loading. Without some compounding variable, such as hereditary hemochromatosis trait, iron loading without transfusion is not generally seen with conditions such as sickle cell anemia or hereditary spherocytosis, in which the erythroid cells mature and leave the bone marrow before they are destroyed.

Consequences of Iron Overload

Iron-induced injury to certain organs, including the liver and heart, can be fatal. Few notable symptoms precede advanced injury. Abdominal discomfort, lethargy, depression, arthralgias, erectile dysfunction, and fatigue are common but nonspecific complaints. Dyspnea with exertion and peripheral edema indicate significant cardiac compromise and reflect advanced iron loading.

As the major site of iron storage, the liver is a conspicuous target for excessive iron deposition. Mild to moderate hepatomegaly develops early, followed by shrinkage produced by fibrosis and micronodular cirrhosis. Hepatic tenderness may be present, but hemosiderotic liver damage produces little inflammation. Consequently, significant hepatic iron deposition and even fibrosis can occur with very little increase in serum transaminase levels. Disturbances in liver synthetic function indicate advanced disease. Liver biopsy is still the "gold standard" for determining the extent of hepatic iron deposition, although noninvasive imaging techniques do have a role. Hematoxylin-eosin staining reveals a brownish pigment in the hepatocytes that staining with Perls Prussian blue unmasks as iron. Large amounts of iron are also deposited in Kupffer cells in patients with ferroportin disease, African iron overload syndrome, or transfusional iron overload. Electron microscopy reveals substantial hemosiderin aggregates in addition to large quantities of ferritin, often in lysosomes.

Congestive cardiomyopathy is the most common heart problem that occurs with iron overload, but other abnormalities have been described, including pericarditis, restrictive cardiomyopathy, and angina without coronary artery disease.[423-426] There is strong correlation between the cumulative number of blood transfusions and functional cardiac derangements in children with thalassemia.[427] Findings on physical examination are surprisingly benign, even in patients with heavy cardiac iron deposition. Once evidence of cardiac failure appears, however, heart function deteriorates rapidly, and medical intervention is frequently ineffective. Biventricular failure produces pulmonary congestion, peripheral edema, and hepatic engorgement. These potentially lethal cardiac complications have, in some cases, been reversed by vigorous iron extrication.[428]

Iron deposition in the bundle of His and the Purkinje system can lead to conduction defects.[429,430] Sudden death is common in these patients, presumably as a result of arrhythmias. At one time, patients treated with the chelator deferoxamine for transfusional iron overload received supplements of ascorbic acid in the range of 15 to 30 mg/kg/day to promote iron mobilization. Reports of sudden death prompted cessation of this practice.[431] Given carefully at lower doses (2 to 4 mg/kg) by an experienced practitioner, ascorbic acid is a safe adjunct to chelation therapy in patients with transfusional iron overload.

Cardiac dysfunction can also occur with very little tissue iron deposition. The total quantity of iron is less important than the unbound, or “toxic,” iron fraction in the circulation. The concentration of unbound iron in tissues is extremely low and virtually impossible to measure. This toxic iron is precisely the component that is bound and neutralized by iron chelators. Therefore, cardiac damage is best prevented in patients with transfusional iron overload by maintaining a constant, low level of chelator in the circulation (and consequently in the tissues where the protection is rendered).

Dysfunction of the endocrine pancreas is common in patients with iron overload.[432,433] Overt diabetes mellitus requiring insulin therapy develops in some patients. The disturbances in carbohydrate metabolism may be more subtle, however. An oral glucose tolerance test often unmasks abnormal insulin production. Vigorous removal of excess iron may reverse the islet cell dysfunction.[434] Exocrine pancreatic function, in contrast, is usually well preserved.

Pituitary dysfunction may produce several endocrine disturbances.[435] Reduced gonadotropin levels are common. When coupled with primary reductions in gonadal synthesis of sex steroids, sexual maturation is delayed in children with transfusional iron overload.[436] Secondary infertility is common. Although Addison syndrome is uncommon with iron overload, production of adrenocorticotropic hormone is occasionally deficient. A metapyrone stimulation test shows delayed or diminished pituitary secretion of this hormone.[437] Thyroid function is usually well preserved in patients with iron overload. In contrast, parathyroid activity is frequently compromised. Functional hypoparathyroidism can be demonstrated in many patients by inducing hypocalcemia with an intravenous bolus of ethylenediaminetetraacetic acid (EDTA) while monitoring the production of parathyroid hormone.[438]

Hyperpigmentation is a nonspecific skin response to a variety of insults, including excessive exposure to ultraviolet light, thermal injury, and drug eruptions. Cutaneous iron deposition enhances melanin production by melanocytes. Ultraviolet light exposure and iron are often synergistic in the induction of skin pigmentation, and, consequently, many patients with siderosis tan very readily. Fair-skinned people who tan poorly may never exhibit hyperpigmentation despite very large body iron burdens. In contrast, a striking, almond-colored hue frequently develops in patients with moderate baseline pigmentation. With a particularly heavy iron overload, visible iron deposits sometimes appear in the skin as a grayish discoloration.

Arthropathy is a common problem in patients with hereditary hemochromatosis but rare in patients with secondary iron overload.[439,440] Patients with hemochromatosis typically exhibit involvement of small joints, particularly in the hands, but large joints, such as the hip, may also be involved. Chondrocalcinosis is a late but characteristic feature of the arthropathy seen in hereditary hemochromatosis. Other troubling musculoskeletal problems include severe, recurrent cramps and disabling myalgias. Muscle biopsy shows iron deposits in myocytes, but the pathophysiologic connection to the pain and cramps is unclear.

Iron Overload and Opportunistic Infections

Withholding iron from potential pathogens is believed to be a natural part of the host defense repertoire.[441] Because transferrin binds iron with extremely high affinity and two thirds of the iron-binding sites of the protein are normally unoccupied, there is very little free iron available in plasma and extracellular fluids. Not surprisingly, both transferrin and its homologue lactoferrin are bacteriostatic in vitro for many bacteria.[442-444] However, the very high transferrin saturations attained in patients with iron overload compromise the bacteriostatic properties of the proteins, and transferrin can serve as a source of iron for some microorganisms.[445] Various infections with unusual organisms have been reported in patients with iron overload (Box 11-4).[446-449] Host defense is compromised even further in patients with sideroblastic anemia and secondary iron overload because of abnormal neutrophil function. Although aggressive antimicrobial therapy is often successful, some infections, such as the mucormycosis produced by *Rhizopus oryzae*, are usually fatal.

Acute Iron Poisoning

Acute iron poisoning from the accidental ingestion of large doses of medicinal iron is a medical emergency. Significant gastrointestinal symptoms occur with doses as

low as 20 mg/kg of elemental iron, and systemic toxicity becomes evident with ingestions of 60 mg/kg (reviewed by McGuigan[450]). Treatment consists of removing as much residual iron as possible from the gastrointestinal tract and administering intravenous deferoxamine, which chelates the toxic NTBI.[450,451] It is appropriate to consult a toxicologist or poison center for assistance.

DISORDERS OF IRON UTILIZATION

Iron Abnormalities in the Anemia of Inflammation

The anemia of inflammation, also called the anemia of chronic disease, is a well-recognized condition associated with a broad spectrum of maladies. It was elegantly described in a classic review by Cartwright almost half a century ago,[452] and is covered in greater depth in Chapter 37. This chapter will focus on the iron abnormalities associated with the disorder.

The anemia of inflammation typically manifests as a mild to moderate, normochromic and normocytic anemia, with a slightly elevated RDW. A mild anisocytosis is often the only hint on the blood smear that the anemia is due to insufficient iron available for erythropoiesis. Serum iron and serum transferrin levels are usually low. Serum ferritin levels are generally increased but may not be when coexistent with iron deficiency. Similarly, sTfR levels are normal unless iron deficiency accompanies the disorder. Not surprisingly, the diagnosis of anemia of chronic inflammation may be challenging to make. Inflammation is the key to the condition.

Bone marrow examination with Perls Prussian blue stain usually reveals deposits of iron in macrophages. This characteristic feature of the anemia of chronic inflammation reflects ineffective iron recycling. Erythroblasts that fail to mature properly and effete erythrocytes are engulfed by macrophages in the marrow, liver, and spleen. The phagocytes degrade the protein and lipid and recycle the iron from hemoglobin onto transferrin for reuse. The anemia of chronic inflammation disturbs this cycle, with iron left trapped in the reticuloendothelial macrophages.

Much has been learned about the pathogenesis of the anemia of chronic inflammation over the past few years. Initially, studies of patients with glycogen storage disease type 1 complicated by anemia and hepatic adenomas provided a clue that increased hepcidin expression might account for both the reticuloendothelial block and the decreased intestinal iron absorption characteristic of the anemia of inflammation.[46] Subsequent investigations confirmed that hepcidin expression was elevated in patients with inflammation associated with a variety of infectious and noninfectious conditions.[44,453] Hepcidin production is induced by the inflammatory cytokine interleukin-6 through a direct effect on the hepcidin promoter.[47-49,454]

Patients with the anemia of chronic inflammation may have unusually low plasma erythropoietin levels for their degree of anemia.[455] This finding was previously attributed to proinflammatory cytokines, which were shown to suppress production of erythropoietin by cells in culture.[456] However, erythropoietin responsiveness is also suppressed in an animal model of anemia of inflammation developed by transgenic expression of hepcidin in noninflamed animals.[457] In addition, hepcidin has been reported to have a direct effect on erythroid colony formation in vitro.[458] However, a decreased response to erythropoietin is likely also a consequence of direct effects of inflammatory cytokines on erythropoiesis. Taken together, these findings suggest that induction of hepcidin in response to inflammation results in most, but not all, of the characteristic features of the anemia of inflammation.

Control of the inflammation (e.g., by colectomy in patients with ulcerative colitis) usually eliminates the anemia and corrects the disturbances in iron metabolism. In general, the anemia is recalcitrant when the inflammation is uncontrolled. However, it is likely that new treatment strategies will be developed that take advantage of our current understanding of the pathogenesis of the anemia of inflammation and regulation of hepcidin production.

SIDEROBLASTIC ANEMIAS

The sideroblastic anemias are a heterogeneous group of congenital and acquired bone marrow disorders defined by the presence of pathologic iron deposits within the mitochondria of erythroid precursors. On Prussian blue, or Perls, iron-stained bone marrow aspirate smears or biopsies, these iron-encrusted mitochondria appear as coarse granules that typically form a halo or "ring" around the nucleus, thus giving rise to the term "ringed sideroblast," which is, by definition, an abnormal cell[459] (Fig. 11-9). Mitochondrial localization of the iron deposits can be confirmed by electron microscopy, but it is not used routinely for diagnostic purposes. "Siderocytes" are mature, enucleated erythrocytes that contain stainable iron, which may be the consequence of residual mitochondria from ringed sideroblasts or cellular ferritin, organelle, and nucleic acid concretions left over from terminal erythroid maturation.[459] Both are recognized as "Pappenheimer bodies" on conventional Wright-Giemsa–stained peripheral blood smears and are abundant in patients with sideroblastic anemia and a number of other anemias, including thalassemia syndromes and hemoglobinopathies.

In addition to the obligatory ringed sideroblasts, the bone marrow in patients with sideroblastic anemia is typically hypercellular with an erythroid hyperplasia. Ineffective erythropoiesis frequently eventuates in elevated body iron stores and may be so severe that it results

in clinically significant iron overload with secondary organ dysfunction. All patients are anemic, and thrombocytopenia and neutropenia develop in some, particularly acquired, neoplastic forms. The anemia may be normocytic, microcytic, or macrocytic and is typically characterized by a relative reticulocytopenia (Table 11-3, reviewed by Fleming[460] and Bottomley[461]).

Congenital Sideroblastic Anemias

Genetically defined, congenital sideroblastic anemias (CSAs) may be inherited in an autosomal recessive, an X-linked recessive, or, infrequently, a maternal fashion (reviewed elsewhere[460-462]). Many cases of congenital sideroblastic anemia are considered to be inherited conditions but defy genetic characterization at the present time. In classifying the known causes of CSA, it is helpful to consider the MCV of the anemia, whether other hematopoietic cell lineages are affected, and whether syndromic associations or other distinctive clinical findings are present (see Table 11-1). Currently, the molecular genetic basis of approximately 60% of cases of CSA can be ascertained.

X-Linked Sideroblastic Anemia

X-linked sideroblastic anemia (XLSA) is the prototype of all congenital sideroblastic anemias (CSAs). As the name implies, the disorder is linked to the X chromosome and disproportionately affects men and boys, although females

may be affected because of skewed X-chromosome inactivation or Turner syndrome.[463-465] The cardinal features of XLSA include (1) a microcytic, hypochromic anemia with a large RDW and erythrocyte dimorphism (particularly in carrier females) and Pappenheimer bodies apparent on the peripheral blood smear; (2) an abundance of ringed sideroblasts, especially in late erythroid precursors; and (3) a variable clinical response to pharmacologic doses of pyridoxine (vitamin B_6).[461] Systemic iron overload may also develop as a result of chronic, severe, ineffective erythropoiesis.[466,467] Importantly, clinically affected females often present at a later age and most commonly have a macrocytosis, rather than a microcytosis, necessitating a distinction between this disorder and acquired neoplastic sideroblastic anemia (see below). Nearly all patients with XLSA have missense mutations in the protein-coding regions of the erythroid-specific isoform of the heme biosynthesis enzyme δ-aminolevulinic acid synthase (ALAS2) (reviewed elsewhere[460,461]). Clinically affected females may harbor nonsense or frameshift mutations.[468] A minor subset of patients have mutations in a GATA transcription factor–binding site within a transcriptional enhancer element located in intron 1 that results in decreased *ALAS2* transcription.[469,470] Rare individuals are reported to have promoter mutations, but this element has not been well validated and the variant occurs at a low frequency in normal populations.[471] ALAS2 missense mutations tend to cluster in amino acids surrounding the catalytic site or the subunit interface of the homodimer, thereby leading to enzymes with decreased stability or decreased affinity for the cofactor pyridoxal phosphate, which can account for the clinical response to large doses of pyridoxine.[472] Because ALAS2 is the rate-limiting step in heme biosynthesis in the erythron, mutations inevitably impair the production of heme in developing erythroblasts. How heme deficiency leads to the hallmark ringed sideroblast is uncertain; however, the characteristic hypochromia and microcytosis are almost certainly the result of the protean effects of heme on erythroid transcription, mRNA stability, and translation.

The age at clinical onset of XLSA varies greatly. Anemia develops in some individuals within a few months of birth, whereas in others it occurs later in childhood and often even in adulthood. Generally, the anemia is progressive, with transfusions often required to maintain an adequate hemoglobin level. Frequent transfusions can hasten the development of iron overload. Oral pyridoxine therapy is useful in many patients with XLSA. Often, however, correction of the anemia is incomplete. Some patients become more pyridoxine responsive after their excess body iron stores are depleted.[473] A few children who failed pyridoxine therapy have responded to the parenteral administration of pyridoxal-5-phosphate.[474] Unfortunately, many children with XLSA improve little, if at all, with either of these interventions. Because pyridoxine is inexpensive and lacks deleterious side effects, all children with sideroblastic anemia should receive a trial of vitamin therapy. Splenectomy is ill advised because of thrombotic risks.[461] There is one case report of successful allogeneic peripheral stem cell transplantation for refractory sideroblastic anemia.[475]

X-Linked Sideroblastic Anemia with Ataxia

X-linked sideroblastic anemia with ataxia (XLSA/A) is a very rare, distinct, X-linked form of sideroblastic anemia caused by missense mutations in the mitochondrial ATP-binding cassette transporter ABCB7.[476-478] Patients with XLSA/A typically have static or slowly progressive cerebellar ataxia and only later are found to have a mild sideroblastic anemia with morphologic features similar to those of classic XLSA.[479,480] However, they do not require transfusion therapy, systemic iron overload does not develop, and they do not respond to pyridoxine therapy. ABCB7 and its yeast orthologue Atm1p are essential genes involved in the biogenesis of cytosolic Fe/S clusters.[481-487] Interestingly, another protein implicated in Fe/S cluster biogenesis in yeast and zebrafish, GLRX5, has been shown to be mutated in a single patient with severe sideroblastic anemia and iron overload.[488-490] In all cases, these Fe/S cluster biogenesis mutants appear to disrupt regulation of IRP1 RNA-binding activity,[487,489] thus raising the possibility that this is a common mechanism for the development of sideroblasts.

Thiamine-Responsive Megaloblastic Anemia

Children with thiamine-responsive megaloblastic anemia (TRMA), also known as Rogers syndrome, exhibit a characteristic triad of megaloblastic anemia with ringed sideroblasts, diabetes mellitus, and deafness.[491,492] The clinical manifestations of TRMA are progressive and may also include optic atrophy and nonthrombotic, nonembolic strokes. The anemia is characteristically macrocytic, and erythroid maturation in bone marrow, as the name implies, is megaloblastic and associated with variable numbers of ringed sideroblasts. Patients may also have leukopenia. The gene responsible for TRMA encodes a transmembrane thiamine transporter designated SLC19A2.[493-496] TRMA patients are not thiamine deficient but rather have a defect in high-affinity thiamine uptake in a number of cell types.[497] The megaloblastic marrow maturation is probably related to defective thiamine-dependent steps in nucleic acid synthesis[498]; however, the pathogenesis of sideroblasts remains obscure. Therapy with pharmacologic doses of thiamine ameliorates the anemia and may abrogate progression of the neurologic and pancreatic phenotypes.[491,499,500]

Pearson Marrow-Pancreas Syndrome

Pearson marrow-pancreas syndrome (PMPS) is a fatal, multisystem disorder of infancy with marked disturbances in bone marrow and pancreatic function.[501] The initial manifestation is often a severe, transfusion-dependent macrocytic anemia associated with a variable degree of neutropenia and thrombocytopenia. Marrow examination shows vacuolization in the erythroid and myeloid precursors and ringed sideroblasts.[502] Exocrine pancreatic dysfunction as a result of pancreatic fibrosis is characteristic, and hepatic, renal, and neurologic dysfunction develops in some patients as well. The variability and pleiotropy of the disorder can be accounted for by the fact that PMPS is a mitochondrial cytopathy; nearly half of the patients share heteroplasmy for a common deletion of approximately 5 kb of mitochondrial DNA (mtDNA) that is associated with other mitochondrial disorders, particularly Kearns-Sayre syndrome; the distribution of defective mitochondrial genomes will necessarily influence expression of the disorder.[503,504] Interestingly, nearly all mtDNA deletions associated with PMPS include the deletion of one of the mitochondrial transfer RNA (tRNA) genes, emphasizing the effect that the pathogenetic mutations could have on the synthesis of multiple mitochondrially-encoded proteins. Whatever the specific target proteins, defective energy production appears to be the central disturbance, and no treatment other than supportive care currently exists.

Mitochondrial Myopathy with Lactic Acidosis and Sideroblastic Anemia

Mitochondrial myopathy with lactic acidosis and sideroblastic anemia (MLASA) is a recently recognized autosomal recessive disorder of mitochondrial dysfunction caused by mutations in the genes encoding pseudouridine synthase 1 (PUS1) or the mitochondrial tyrosyl-tRNA synthase (YARS2).[505-512] Most cases of PUS1 deficiency are associated with a unique founder mutation present in the Persian-Jewish population, and several cases of YARS2 deficiency have been reported in individuals of Lebanese-Christian descent. Insufficient numbers of patients with MLASA have been characterized to distinguish individuals with one or the other mutated gene; however, even within genotypes and allelotypes, patients with MLASA may have highly variable neurologic abnormalities that most characteristically consist of exercise intolerance and lactic acidosis but may include severe hypotonia, muscle wasting, developmental delay, and mental retardation. The anemia, which is typically slightly macrocytic, is equally variable despite a common genotype, with some patients having asymptomatic anemia and others requiring transfusional support. PUS1, which localizes to mitochondria, the cytosol, and the nuclei, is one of several enzymes that modify uridine residues in long-lived RNA (e.g., tRNA) to the alternate base pseudouridine. This modification is thought to enhance the stability of these molecules and enhance protein translation. YARS2, by contrast, is solely a mitochondrial enzyme and appears to uniquely have effects on mitochondrial protein synthesis.[511]

Other Forms of Congenital Sideroblastic Anemia

At the present time, the genetic basis of approximately 40% of cases of CSA remains unexplained. Doubtless there are other syndromic and nonsyndromic sideroblastic CSAs to be molecularly characterized. Numerous patients with syndromic associations with other phenotypes associated with mitochondrial cytopathies, such as neurodevelopmental impairment, myopathy, hepatopathy, hypotonia, and failure to thrive, have been described. These patients most often have macrocytic sideroblastic anemia, often associated with other cytopenias, and very much resemble Pearson marrow-pancreas syndrome. Very recently, a syndromic form of microcytic sideroblastic anemia associated with recurrent, aseptic, febrile inflammatory episodes, hypogammaglobulinemia, and developmental delay has also been described (sideroblastic anemia, immunodeficiency, fever, and developmental delay [SIFD]).[513]

Acquired Sideroblastic Anemias

A number of drugs and toxins that impair heme biosynthesis or perturb mitochondrial iron metabolism can produce sideroblastic anemia (Box 11-5) (reviewed by Ammus and Yunis[514]). Whereas chronic alcohol abuse is the most common toxin associated with sideroblastic anemia in adults, the most important of these agents in the context of pediatrics is lead. This element inhibits several enzymes in the heme biosynthetic pathway, including δ-aminolevulinic acid dehydratase, coproporphyrinogen oxidase, and ferrochelatase.[515] Lead screening, therefore, is mandatory in any child suspected of having sideroblastic anemia because lead poisoning can be treated. Isoniazid also produces sideroblastic anemia by causing functional depletion of pyridoxine, which inhibits heme biosynthesis.[516,517] Prophylactic treatment with pyridoxine is now part of the standard therapeutic regimen with this drug.

Acquired, clonal neoplastic sideroblastic anemias such as refractory anemia with ringed sideroblasts (RARS) and other myelodysplastic syndromes (MDSs) are exceptionally uncommon in the pediatric age group, except perhaps in children who have previously received chemotherapy for cancer.[518] In fact, RARS is so rare in individuals younger than 40 years of age that a thorough investigation of potential congenital conditions or toxic causes of sideroblastic anemia should be made in persons of this age group, particularly in the absence of clonal cytogenetic abnormalities or specific somatic mutations (see below). The extent to which the considerable experience with MDS in adults might be applicable to children is uncertain; however, when compared with other categories of MDS, RARS has a lesser propensity to evolve to acute leukemia and may often be associated with iron overload in the absence of significant transfusional support.[519] Intriguingly, some patients have been shown to have mutations within the mitochondrial genome that alter the coding sequence for cytochrome *c* oxidase.[520]

High throughput genomic sequencing technologies have recently showed that approximately two thirds of patients with RARS or other forms of MDS and myeloproliferative neoplasms with smaller numbers of ringed sideroblasts have heterozygous somatic mutations in splicing factor 3 subunit B1 (SF3B1).[521-524] All mutations, including the most common variant that substitutes a glutamic acid for a lysine at position 700, cluster in the region of the protein, indicating that it is highly likely that this is a gain-of-function mutation. Which, if any, of the CSA genes are involved in the pathogenesis of this disorder is uncertain; however, early reports suggest that ABCB7 is among the mRNAs that are abnormally processed and expressed in RARS.[525-527]

COPPER METABOLISM

Copper Physiology and Transport

A total of 100 to 150 mg of copper is present in an adult human. As with iron, the fetus accumulates large amounts of copper near the end of gestation, particularly in the liver, where concentrations are 5 to 10 times greater at birth than in adulthood. These stores do not decrease to adult levels until 5 to 15 years of age. The liver has the highest copper content, which together with muscle and bone, accounts for 50% to 75% of total body copper. The normal net copper intake is 2 to 5 mg in an adult and 0.04 to 0.15 mg/kg in a growing child. After about 6 months of age, normal plasma copper levels range between 70 and 140 mg/dL. Values are lower in early infancy.[528] Depressed plasma copper levels are a good indicator of early copper deficiency; however, functional tests of enzymatic activity (e.g., ceruloplasmin) may be better.

Like iron, copper is essential for normal cell growth and metabolism but toxic in excess. Unlike iron, however, copper balance is regulated by excretion as well as by absorption.[529,530] The gastrointestinal tract absorbs about 30% of the copper present in an average diet. The liver promptly disposes of much of that copper in bile, whereas a lesser amount is lost through the intestinal mucosa.[531]

Plasma copper, which is held much more constant than plasma iron, exists in two forms. Albumin and amino acids loosely bind 10% to 15% of circulating copper. Ceruloplasmin, a multicopper ferroxidase, tightly binds the remaining copper in plasma. Ceruloplasmin was once thought to be a copper transport protein; however, it is now clear that it functions primarily to change the oxidation state of iron, thereby aiding in release of iron from storage cells, including hepatocytes and macrophages (as discussed earlier). In human patients[532-535] and mice[89] lacking ceruloplasmin, a distinct clinical syndrome characterized by neurodegeneration, hepatic iron overload, diabetes, impaired iron recycling by reticuloendothelial cells, and mild iron deficiency anemia develops.

Copper is an essential component of cytochrome oxidase, the terminal oxidase of the electron transport chain required for combining hydrogen with oxygen to form water. As such, the element is essential for the oxidative generation of ATP. The enzyme tyrosinase is a copper-containing protein required for the synthesis of melanin. Thus, copper-deficient animals have depressed levels of cytochrome oxidase in most tissues, along with loss of hair pigment. Another copper metalloenzyme, lysyl oxidase, plays a role in the cross-linking of collagen and elastin. Lysyl oxidase deficiency may cause the vascular defects, including aortic aneurysm, seen in copper-deficient animals and patients with Menkes disease (see later).[529]

Copper trafficking is relatively well understood (reviewed by Kim and colleagues[536]). A multi–transmembrane domain protein, CTR1, appears to be the major transporter that brings copper into mammalian cells.[537-539] Knockout mice lacking CTR1 die early in gestation, with findings that may be attributable to severe copper deficiency. Once copper is inside cells, it moves to its sites of use escorted by specific chaperone proteins (reviewed elsewhere[540,541]). These proteins appear to be conserved from yeast to mammals. Targeted disruption of one of these proteins, Atox1, in mice leads a poorly viable, copper-deficient phenotype, thus indicating that its copper chaperone function is important but not essential.[542]

Two inherited defects of human copper metabolism have given insight into copper transport within cells. Menkes disease, or Menkes kinky hair syndrome, is a congenital disorder characterized by a low serum copper concentration, reduced activity of copper metalloenzymes, slow growth, hypopigmented kinky hair, cerebral degeneration, and an X-linked pattern of inheritance.[543] Parenteral copper administration, like all other attempts to treat the disease, is ineffective, and death before 3 years of age is typical. By contrast, in the autosomal recessive disorder Wilson disease, the predominant clinical phenotypes—liver disease, hemolysis, and neurodegeneration—are due to copper cytotoxicity.

Positional cloning led to identification of the genes mutated in Menkes and Wilson diseases.[544-546,547,548,549] Each is a P-type adenosine triphosphatase transmembrane copper transporter (Cu-ATPase) containing Gly-Met-Thr-Cys-X-X-Cys copper-binding motifs at their N-termini. The Menkes protein, ATP7A located on chromosome Xq21.1, is involved in transport of copper in intestinal enterocytes, as well as a number of other cell types. Deficiency of the Menkes proteins leads to paradoxic systemic copper deficiency as a result of impaired intracellular intestinal copper transport accompanied by intracellular copper accumulation in certain cell types, particularly the kidney. By contrast, deficiency of the Wilson disease Cu-ATPase, ATP7B located on chromosome 13q14.3, leads to cellular copper accumulation in the liver, basal ganglia, and kidney, along with impaired production of ceruloplasmin and hepatobiliary copper excretion. Interestingly, although Menkes disease patients are copper deficient, anemia is not a prominent feature of the syndrome (see below). Wilson disease may be manifested in children as fulminant hepatic failure associated with severe acute intravascular hemolysis (see below).[550,551]

Hematologic Aspects of Copper Deficiency

Copper deficiency commonly causes hypochromic, microcytic anemia among farm animals in areas of the world where the soil is poor in copper.[552,553,554,555] In humans, the predominant clinical feature of copper deficiency is peripheral neuropathy. Because of milk's low copper content (about 0.12 mg/L), infants who consume a diet consisting largely of milk may be at risk for marginal copper nutrition or deficiency.[556] Nutritional copper deficiency can be due to extraordinary dietary circumstances, such as inadvertent omission of copper from intravenous alimentation formulations for an extended time or treatment of severely malnourished patients with a copper-deficient milk diet.[529,530,557] Impaired copper absorption may be a consequence of a variety of renal and gastrointestinal disturbances, including nephrotic syndrome, inflammatory bowel disease and other forms of malabsorption, or bariatric or other intestinal surgery.[558,559] Excessive zinc supplementation or ingestion of coins containing zinc may also lead to copper deficiency because zinc readily induces intestinal epithelial metallothionein, which preferentially chelates intestinal copper and prevents absorption.[529,560] Coexisting iron deficiency or severe malnutrition can obscure the manifestations of copper deficiency.

In humans, the anemia of copper deficiency is most typically normocytic, but it may be microcytic or macrocytic. Leukopenia with very marked neutropenia is particularly prevalent; thrombocytopenia is unusual. Bone marrow aspirates from copper-deficient individuals are often hypocellular and show a relative erythroid hyperplasia with prominent vacuolization of erythroid precursors and variable degrees of dyserythropoiesis or megaloblastoid changes (or both), with or without the presence of ringed sideroblasts. As many recent reports indicate, resistance to treatment with typical hematemics combined with the morphology may suggest the errant diagnosis of MDS (reviewed by Haddad and associates[561]). The coexistence of peripheral neuropathy, also typical of copper deficiency, may suggest the correct diagnosis. Osteoporosis may occur with severe copper deficiency.

Oral treatment with 0.1 to 0.3 mg/kg of copper per day (two or three times the estimated daily requirement) as 0.5% copper sulfate (containing about 2 mg of copper per milliliter) produces prompt reticulocytosis and correction of the anemia and neutropenia. Intravenous copper may also be given in severe deficiency states. Generally, the dietary imbalance that produced the deficiency can be corrected when the problem is recognized.

Hematologic Aspects of Acute Copper Intoxication and Wilson Disease

Oxidant damage is incurred by the red cell membrane in a variety of inherited disorders involving abnormal hemoglobins that create defects in the cells' endogenous system for detoxification of oxidants. These include sickle cell disease, thalassemias, unstable hemoglobinopathies, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and disorders of glutathione metabolism. Membrane oxidant damage may also result from encounters with exogenous oxidants, such as copper. Acute copper-induced hemolysis has been reported in humans after accidental or suicidal ingestion of copper or copper-containing compounds, copper sulfate therapy for burns, copper contamination of hemodialysis units, and Wilson disease.[562-568] In the first three instances, acute intoxication is characterized by flushing, chills, nausea and vomiting, diarrhea, abdominal pain, a metallic taste in the mouth, excessive salivation, headache, weakness, and acute intravascular hemolysis.[562-567,569]

Wilson disease is an autosomal recessive disorder of copper metabolism, presenting between 3 and 52 years of age, and characterized by defective biliary excretion of copper, low plasma levels of ceruloplasmin, and toxic accumulation of copper in the liver, erythrocytes, kidneys, cornea, and brain.[570,571] The clinical consequences of toxic copper overload include cirrhosis, hemolysis, corneal Kayser-Fleischer rings, and a progressive neurologic syndrome.[572-585] Early diagnosis followed by effective treatment can lead to reversal of clinical symptoms, including hemolysis.

Hemolysis is an early feature of Wilson disease; it is seen in about 20% of patients with liver disease[572] and may be the presenting manifestation of the disorder.[573-580,586-590] Because the disease is treatable and because hemolysis may presage fulminant liver disease by days to years,[576,578,579] the clinician must always consider Wilson disease in children and young adults with Coombs-negative hemolytic anemia both with and without overt liver disease. Thrombocytopenia may also occur,[591] and patients have been misdiagnosed as having thrombotic thrombocytopenic purpura or hemolytic uremic syndrome. Typically, these previously well children have chemical evidence of liver disease, mild hepatosplenomegaly, a low ceruloplasmin concentration, increased erythrocyte and hepatic copper levels, and increased urinary copper excretion. Jaundice is often seen and may be severe. The hemolysis observed in Wilson disease is acute, but the clinical features, although similar to those of acute copper poisoning, are usually more subtle. Hemoglobin may be detected on urinalysis, but gross hemoglobinuria is unusual. Peripheral blood smears do not usually show characteristic changes, although spur cells and target cells have been documented in patients with concurrent severe liver disease.

The Wilson disease gene, the copper-transporting ATPase, ATP7B, and the Wilson disease protein, WNDP, belong to the large family of cation-transporting P-type ATPases.[591-596] A wide variety of mutations have been described in this gene in patients with Wilson disease.[597-600] The belief is that, in Wilson disease, copper initially accumulates in hepatocytes because of the absence of the copper-transporting protein, which is required for the incorporation of copper into ceruloplasmin. Copper eventually reaches a toxic level in the liver and is released into the bloodstream by hepatocellular necrosis.[578] Plasma copper is rapidly taken up by red cells.[601] Intravascular hemolysis occurs as a consequence of oxidative damage. The oxidative effects of copper are manifold. In vitro, copper inactivates numerous red cell glycolytic and hexose monophosphate shunt enzymes; directly oxidizes reduced NADPH and glutathione; oxidizes and denatures hemoglobin; damages membrane ATPases, fatty acid acylase, and probably other membrane enzymes; generates lipid peroxides; and cross-links membrane skeletal proteins into disulfide-bonded high–molecular-weight complexes, increasing membrane permeability and rigidity.[579,602] However, many of these effects have not been demonstrated at concentrations of copper observed in hemolyzing erythrocytes (150 to 400 mg/dL of red cells = 2.4 × 10–5 to 6.3 × 10–5 mol/L).[580,584] In vivo studies have indicated a marked inhibition of hexokinase and G6PD from red blood cells in patients with untreated Wilson disease compared with patients taking penicillamine and healthy children.[603] In addition, decreased glutathione levels were found in patients with untreated Wilson disease, as well as decreased antioxidant enzymes such as superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase. Although it has so far not been possible to determine the exact cause of the demise of red cells, initial studies indicate that free copper (non–ceruloplasmin bound) leads to oxidative injury resulting in altered erythrocyte metabolism and antioxidant status in patients with Wilson disease. Whatever the pathophysiology of the hemolysis may be, several case reports suggest a role for therapeutic plasma exchange in acute wilsonian hemolytic crisis, if only as a bridge to hepatic transplantation.

LEAD TOXICITY

Sources of Lead

Lead is a toxic metal without any function in the human body. Because of its useful properties, lead has been mined for several centuries. As a result, progressively larger amounts have been removed from the depths of the earth and introduced into the biosphere. Enough lead has found its way into humans that at least in the industrialized parts of the world, all people have some lead in the body and hence in the blood. It has thus become customary to refer to the blood lead values found in apparently healthy populations as “normal” blood lead levels. This term is an obvious misnomer because it implies some kind of minimum physiologic requirement for lead.

Airborne lead enters the human body through inhalation; about 35% is absorbed and 15% to 18% is retained.[604] Intake of airborne lead is greater in children because they breathe at a lower height, where the lead concentration is greater, and have a greater respiratory rate per unit of body weight.[605] Sources of inhaled lead include combustion engines that burn leaded fuel and primary and secondary (recycling) lead smelters. Lead can also be ingested through the intake of contaminated food, water, and beverages. Lead absorption is increased by deficiencies of essential minerals, such as iron and calcium.[606] High maternal lead levels can result in fetal lead toxicity.[607]

Children living in older houses are exposed to the additional risk of lead in paint. Although lead in air, food, and beverages can be considered *low-dose sources*, lead in paint is by far the most concentrated source. As much as 40% of lead by weight is present in dried paint used before World War II. Since then, lead levels in paint have been progressively reduced. For many years it was believed that lead poisoning in children occurred primarily as a result of pica (the urge to ingest nonfood material), with consequent ingestion of paint chips.[608] Although this is not an uncommon occurrence, it is neither the only nor even the prevailing mechanism of ingestion of lead paint. Small children, through their ordinary hand-to-mouth activities (such as thumb sucking) directly ingest dust and thus take in large amounts of lead. Despite legislative efforts and scientific advances in the United States, millions of dwellings still contain leaded paint. These dwellings present an obvious risk, particularly to children of the poor, who tend to live in the oldest houses. The state of repair of the dwelling is almost as important as the lead content of the paint; peeling or flaking paint is obviously more accessible to small children. Because iron deficiency often induces pica, lead poisoning is more common in iron-deficient children.

Less common sources of lead include fumes from outdated plumbing; old battery casings; illegally distilled whiskey; printed paper, particularly colored magazines; and lead-painted toys. The traditional Asian, African, and Middle Eastern eye cosmetic *kohl*, as well as a number of traditional or herbal remedies including *azarcon* (*greta*), are substantially composed of lead. An uncommon source of lead that may result in severe poisoning is improperly glazed earthenware vessels used to store acidic beverages such as fruit juices.

Biochemical and Hematologic Effects of Lead

Lead has strong affinity for the sulfhydryl groups of cysteine, the amino group of lysine, the carboxyl groups of glutamic and aspartic acids, and the hydroxyl group of tyrosine. Lead binds to proteins, modifies their tertiary structure, and inactivates their enzymatic properties. Enzymes that are rich in sulfhydryl groups appear to be most sensitive. Mitochondria are particularly sensitive to lead. Many prominent effects of lead on heme synthesis are mediated through alterations of the mitochondrial membrane. Heme synthesis starts and ends inside the mitochondria; intermediate steps take place in the cytoplasm. In all cells, heme is an essential component of molecules of the cytochrome system, also located inside the mitochondria. Additionally, in erythropoietic precursors, very large amounts of heme are formed to make hemoglobin. Lead interferes at several points in the heme synthetic pathway in all cells. The two most important steps affected are those catalyzed by δ-aminolevulinic acid dehydratase (a cytoplasmic enzyme) and ferrochelatase (an intramitochondrial enzyme). Both of these enzymes depend on critical sulfhydryl groups for their activities. The inhibition by lead of ferrochelatase, which catalyzes the ultimate insertion of iron into protoporphyrin, results in the accumulation of protoporphyrins in maturing erythrocytes. Ultimately, despite the presence of a normal or an increased intracellular content of iron, the mitochondria are starved for iron. Metalloporphyrins inhibit several mitochondrial enzymes, and the increased concentration of zinc protoporphyrin resulting from lead toxicity further impairs mitochondrial function.[609] There is a relationship between the concentration of lead that inhibits ferrochelatase in mitochondria and the ambient concentration of iron in the medium. At any concentration of lead, inhibition of ferrochelatase is most marked when the iron concentration is the lowest.[610] This biochemical mechanism explains the greater elevation of erythrocyte protoporphyrin observed, at equal lead exposure, in children with concomitant iron deficiency.[611] A progressive, exponential increase in erythrocyte protoporphyrin concentration is observed at blood lead levels of 5 to 90 μg/dL.[612] The erythrocyte protoporphyrin level is an indicator of adverse metabolic effects. It is very effective as a screening test for severe lead poisoning, but it cannot be used to screen for blood lead levels below 40 to 50 μg/dL.

The bulk of lead in blood (>90%) is contained in erythrocytes, but blood lead content is independent of the hematocrit. Basophilic stippling results from deposition of ribosomal RNA and mitochondrial fragments.[613] Moderate basophilic stippling may be seen in iron deficiency and thalassemia trait, but stippling is particularly prominent in the polychromatophilic erythrocytes in lead poisoning, unstable hemoglobinopathies, including severe β-thalassemia, and pyrimidine-5′-nucleotidase deficiency. Anemia is observed in children with lead poisoning, primarily in severe cases or in those with concomitant iron deficiency.[610] This is not an unexpected finding, because the defect in heme synthesis affects only a very small fraction of the total protoporphyrin production and clinically significant anemia usually develops in the late stages. It is not uncommon to observe severe neurologic toxicity in the absence of anemia in children. On the other hand, lead intoxication and iron deficiency anemia tend to occur in the same lower socioeconomic population and are aggravated by each other. Iron-deficient children are more severely affected because iron deficiency increases lead ingestion through pica, increases lead absorption, enhances the defect in heme synthesis, and increases the toxicity of lead.

Other enzymes of heme biosynthesis are also affected by lead, but less severely. Uroporphyrinogen synthetase activity is inhibited only by a rather high (10^{-4} mol/L) lead concentration.[609] Coproporphyrinogen decarboxylase, another mitochondrial enzyme, also is inhibited by lead.[609] There is a marked increase in urinary coproporphyrin levels in lead intoxication. Measurement of urinary coproporphyrin has been widely used for the diagnosis of childhood lead poisoning, particularly in emergency departments. Although this test has been superseded by the easier measurement of erythrocyte protoporphyrin, it is important to recognize its usefulness in discriminating between recent and past lead exposure. Because of the protracted persistence of protoporphyrin within erythrocytes, significant elevations may be observed as long as 2 to 3 months after exposure to lead.[614] In contrast, increased coproporphyrin production, as a result of its high solubility, is immediately reflected in excess urinary excretion. Hence, when exposure to lead is current, both the erythrocyte protoporphyrin level and the urinary coproporphyrin levels are increased; when exposure to lead is no longer present, there is a discrepancy between the elevated erythrocyte protoporphyrin level and normal urinary coproporphyrin excretion.

The process of heme synthesis is not exclusive to the erythron. All cells contain essential heme proteins, particularly in the respiratory cytochrome system, also located in the mitochondria. The most visible effects of lead on heme synthesis are those detectable in peripheral blood because this is the easiest tissue to sample. However, the ubiquitous presence of active heme synthesis in the mitochondria of all body cells and the affinity of lead for mitochondria result in widespread impairment of cellular function. Lead intoxication inhibits the synthesis of cytochrome P-450, the key enzyme in the mixed oxidase system. It appears likely that the toxic effects of lead, particularly in the nervous system, reflect the derangement in heme synthesis.[615]

In adults, peripheral neuropathy, abdominal colic, and anemia are the most common initial signs of lead poisoning. In children, the clinical effects of excessive exposure to lead are apparent primarily in the central nervous system; alterations in renal function and anemia occur only in the most severe cases. Acute encephalopathy can be the first manifestation of severe childhood lead poisoning. The onset is usually marked by seizures, often intractable, followed by coma and cardiorespiratory arrest. The syndrome may be fatal within 24 to 48 hours. Survivors often suffer permanent neurologic damage.[616] Acute encephalopathy may be accompanied by Fanconi renal tubular syndrome with aminoaciduria, glycosuria, and hyperphosphaturia.[617]

Chronic symptoms of lead toxicity are vague and include abdominal pain, vomiting, general malaise, and behavioral changes. These symptoms are nonspecific and of little diagnostic help, particularly in the youngest children, aged 1 to 3 years, who are the most frequently affected. The threshold blood lead level at which encephalopathy occurs in children is difficult to define. *Acute lead poisoning* with clinical signs other than encephalopathy has been observed at blood lead levels ranging between 60 and 450 μg/dL. On the other hand, it is possible to observe blood lead levels as high as 200 μg/dL in children without overt neurologic symptoms. The probability of overt neurologic problems increases with the blood lead level and becomes significant when the blood lead level rises above 70 μg/dL. For these reasons and because of the impending risk of an unpredictable clinical deterioration, children found to have blood lead levels of 70 μg/dL or greater should be treated as medical emergencies, even in the absence of symptoms.[618]

As a result of the greater awareness of childhood lead poisoning by physicians, extensive screening programs in large cities, and the reduction of lead in the air subsequent to the wider use of lead-free gasoline, severe lead poisoning is extremely rare. Additionally, there is a greater awareness of the subclinical effects of lead and the fact that there is no threshold below which body lead levels can be considered safe. In view of the evidence of adverse effects of exposure to lead, even at low levels, there has been progressive lowering of the "acceptable" blood lead level. Therefore, it is important to not confuse "intervention levels" (decided on pragmatic considerations) with "safe" levels.

The insidious nature of lead toxicity mandates the detection of excessive exposure in apparently asymptomatic children before irreparable damage occurs. Screening for lead poisoning is made particularly difficult by the fact that the most commonly affected children are those of preschool age, who are also the least accessible, as a group, to mass testing. Screening in this age group is most often performed by pediatricians at routine office visits. It would be desirable, instead, for screening programs to reach out to the community and focus on the most economically deprived children, who have the least access to medical care, as well as the highest risk.

Nationwide programs for screening children must be directed primarily at identifying those in need of medical attention. The definition of *lead poisoning* now includes the category of children with blood lead levels of 10 to 19 μg/dL. Yet it has been shown that at this level the potential loss of IQ is so low that most people would agree that it is trivial.[619,620] Although medical intervention is not necessary for this group, educational and dietary advice is recommended. Children in need of medical attention are those with blood lead levels of 20 μg/dL or higher. Above this level, cognitive issues become significant.[619,620] Severe lead poisoning is defined as levels above 45 μg/dL.

Treatment of Lead Poisoning

The first and most essential step in treating childhood lead poisoning is identification and removal of the source of lead. Without elimination of the exposure, any treatment is futile. Environmental analysis, including home visits, is recommended to ascertain and remove the source of lead. Although complete removal of lead from the environment remains a formidable task for modern society, it offers the only viable solution to prevent lead toxicity in children. Multiple studies have shown that neurotoxicity is unlikely to be reversible, regardless of treatment, once lead intoxication is discovered. Because lead exposure is additive, removal of automobile-generated lead from the air has already had a profound impact on the problem of urban lead poisoning. However, residual lead-based paint continues to be a major problem.

Children who are symptomatic require urgent treatment. However, because the symptoms of lead poisoning may be elusive, treatment is indicated even in their absence if there is clear evidence of an excessive body burden of lead. The goal of treatment is prevention of subclinical damage without producing complications of the therapy itself; it is necessary to exercise judicious compromise. Two parenteral treatments are used in severe lead poisoning: dimercaprol (formerly called BAL, for British anti-Lewisite) and calcium disodium-ethylenediaminetetraacetic acid (CaNaEDTA). Both these agents chelate lead and induce its excretion. Dimercaprol is an oily, malodorous compound that is unpleasant to patients. It forms an emetic compound with iron, so iron therapy should not be given to a patient receiving dimercaprol.[621] It is dissolved in peanut oil and thus is contraindicated in children allergic to peanuts. Approximately half of patients treated with dimercaprol have side effects, many of which can be ameliorated by the concurrent use of antihistamines.[618]

CaNaEDTA is water soluble and best administered by continuous intravenous infusion. When administered intramuscularly (a less preferable and much more painful option), 2% procaine should be added to avoid severe local pain. CaNaEDTA may itself be toxic, particularly to the kidneys. Overdosage may induce tubular necrosis directly or renal toxicity as a result of hypercalcemia. CaNaEDTA is also able to chelate zinc, thus presenting another risk. Because δ-aminolevulinic acid dehydratase, a zinc-dependent enzyme, is already damaged by lead, the additional removal of zinc leads to its complete paralysis. This results in a burst of neurotoxic δ-aminolevulinic acid into plasma, which may aggravate (and even induce) convulsions. For these reasons, CaNaEDTA should never be given alone to symptomatic children or to asymptomatic children with blood lead levels of 70 μg/dL or greater; instead, it should be given after administration of dimercaprol to prevent these acute effects.[618] An additional note of caution is necessary with regard to the use of EDTA. Besides CaNaEDTA, a commercial preparation of disodium EDTA is also available and occasionally used for hyperparathyroidism. Disodium EDTA should never be used for the treatment of lead poisoning because it may induce acute hypocalcemia, which may be fatal. Only CaNaEDTA should be used for the treatment of lead poisoning. Hospital pharmacies should exercise maximum caution in dispensing disodium EDTA, which could be fatal if erroneously given to a child with lead poisoning but without hypercalcemia.

Because of their different pharmacologic properties, dimercaprol and CaNaEDTA are advantageously used in combination to treat children with symptomatic lead poisoning, with or without concomitant encephalopathy, as well as asymptomatic children with blood lead levels greater than 70 μg/dL.[618] The combined use of dimercaprol and CaNaEDTA is both safer and more effective than the use of CaNaEDTA alone. Treatment should always start first with dimercaprol to avoid precipitating encephalopathy.[621] Involvement of an experienced toxicologist is strongly advised for safe, effective management of these patients.

Succimer is a derivative of dimercaprol in which the methyl groups are replaced by carboxylic groups. This results in excellent water solubility, allowing it to be used orally. Although the advantages of an oral chelator are obvious, it is crucial to be cautious in the use of succimer because with its great water solubility and affinity for lead, it may result in increased absorption if used in a lead-laden environment. For this reason, succimer should be used only when it is absolutely certain that the child has been removed from the lead-containing environment and is in a safe home. In a recent trial, succimer was shown to be effective in reducing blood lead levels in patients with levels of 20 to 45 μg/dL.[622] Importantly, however, it did not reverse neurologic and cognitive deficits. For this reason, the authors concluded that it is not indicated in children with moderate lead levels (20 to 45 μg/dL). Experience with this drug in treating children with blood lead levels of 70 μg/dL or higher is very limited. In these cases, as well as in symptomatic children, it may still be prudent to treat with a combination of dimercaprol and CaNaEDTA.

Regardless of the treatment, it is important to remember that improvement in blood lead levels does not mean that all lead has been removed. Blood levels are likely to rebound 1 to 2 weeks after therapy as tissue lead (particularly from bone) enters the circulation. Children with a large body burden of lead, such as those with clinical symptoms or blood lead levels in excess of 70 µg/dL, invariably require several cycles of chelation therapy before a substantial reduction in the body burden of lead is obtained.[621] The need for additional cycles of therapy can be established by measurement of urinary lead excretion during the first days of treatment. The lead excreted should be related to the amount of EDTA given. Children who excrete lead in larger proportions are in greater need of additional cycles of therapy. It is not uncommon for a child to require several months of chelation therapy, initially with both dimercaprol and CaNaEDTA and later with CaNaEDTA alone, before urinary lead excretion declines and the blood lead level stabilizes below 30 µg/dL. Only at that point can chelation therapy be stopped.[621]

CHAPTER 12

Porphyrias

John D. Phillips and **James P. Kushner**

CHAPTER OUTLINE

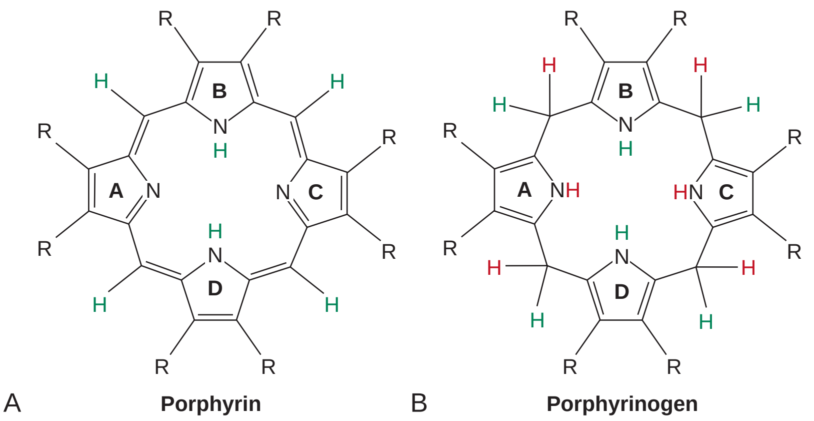
FORMATION OF THE PYRROLE
The δ-Aminolevulinate Synthases
δ-Aminolevulinate Dehydratase
ASSEMBLY OF THE TETRAPYRROLE
Porphobilinogen Deaminase
Uroporphyrinogen III Synthase
MODIFICATION OF THE TETRAPYRROLE SIDE CHAINS
Uroporphyrinogen Decarboxylase
Coproporphyrinogen Oxidase
ENZYMATIC OXIDATION OF PROTOPORPHYRINOGEN IX TO PROTOPORPHYRIN IX AND INSERTION OF IRON
Protoporphyrinogen Oxidase
Ferrochelatase

The porphyrias are caused by reduced activity of enzymes that constitute the heme biosynthetic pathway. With the exception of porphyria cutanea tarda (PCT), all are. Porphyrins are planar molecules comprised of four pyrrole rings connected by four methene groups. Porphyrins are also referred to as *tetrapyrroles* (Fig. 12-1, *A*). Porphyrins are intensely colored compounds (the word *porphyria* is derived from the Greek *porphuros,* meaning red-purple). All porphyrins avidly absorb light in a region of the spectrum known as the Soret band (around 400 nm) because of the alternating single-double bond structure of the porphyrin macrocycle. Once excited by light, porphyrins emit photons in the red region of the spectrum, a phenomenon responsible for their fluorescent properties. The emitted photons mediate the skin damage, which occurs in sun-exposed skin in some of the porphyric disorders.

The porphyrin precursors δ-aminolevulinic acid (ALA) and porphobilinogen (PBG) (a monopyrrole) are colorless compounds that do not fluoresce. Recent evidence suggests that these compounds are responsible for the neurovisceral manifestations of several of the porphyric disorders. A convenient classification scheme divides the porphyric disorders into three groups according to their clinical manifestations (Box 12-1). Alternate schemes have been proposed by which the porphyrias are classified according to the organ in which the enzymatic defect is most apparent (hepatic porphyrias versus erythropoietic porphyrias), but these schemes are less useful to the clinician. Most heme synthesis takes place in erythroid precursors for the generation of hemoglobin, but approximately 15% of the daily production takes place in the liver,[1] mainly for the formation of the cytochrome P450 enzymes. Heme is also a component of numerous other cellular proteins, including cytochromes, myoglobin, catalase, peroxidase, guanylate cyclase, and others, and the heme biosynthetic pathway is functional in all cells.

With the exception of ferrochelatase (FECH), the terminal enzyme in the pathway that catalyzes the insertion of iron into protoporphyrin IX (proto IX), all enzymes in the pathway that utilize cyclic tetrapyrroles require fully reduced porphyrinogens as substrates. Porphyrinogens are flexible, colorless, reduced compounds with hydrogen atoms added to each of the bridge carbons and to nitrogens of the pyrrole rings (Fig. 12-1, *B*). Porphyrinogens are very sensitive to oxidation. When the heme biosynthetic intermediates uroporphyrinogen and coproporphyrinogen are oxidized to the corresponding porphyrins, they can no longer serve as substrates (Fig. 12-2) and are excreted in urine and stool. Protoporphyrinogen oxidase (PPO) also requires the reduced compound protoporphyrinogen as substrate.

Hans Fischer[2] originally developed the currently utilized porphyrin nomenclature. Proto IX was the ninth isomer of protoporphyrin synthesized by Fischer and corresponded to the only isomer of protoporphyrin found in



A Porphyrin

B Porphyrinogen

Figure 12-1 Porphyrin and porphyrinogens. Porphyrins are tetrapyrroles. **A,** Porphyrins are the oxidized form of porphyrinogens. The alternating single-double bond sequence of the molecule imparts the color and fluorescent properties of porphyrins and produces a rigid planar shape. **B,** Porphyrinogens, the reduced form, are colorless, do not fluoresce, and are highly flexible.

nature. Uroporphyrinogen and coproporphyrinogen could occur in four isomeric forms, but only the I and III forms occur in nature. The I and III isomers of uroporphyrinogen differ only in the positions of the acetate and propionate side chains on the D ring (see Fig. 12-1), but only the III isomer can ultimately be converted to proto IX and heme.

In eukaryotic cells, the heme biosynthetic pathway is divided between three compartments: (1) the mitochondrial matrix, (2) the mitochondrial intermembrane space, and (3) the cytosol (see Fig. 12-2). The pathway enzymes have been intensively characterized. All of the genes have been cloned, and many mutations responsible for the porphyrias have been identified. The crystal structures of all of the enzymes have been determined, providing models for the mechanisms of catalysis and the effects of specific mutations (Table 12-1).

Here we will dissect the complex heme biosynthetic pathway into four basic processes, and each porphyric disorder will be described in the context of the process that is defective:

- Formation of the pyrrole
- Assembly of the tetrapyrrole
- Modification of the tetrapyrrole side chains
- Enzymatic oxidation of protoporphyrinogen IX (proto'gen IX) to proto IX and insertion of iron

Box 12-1 Clinical Classification of the Porphyrias

PHOTOSENSITIVITY SYMPTOMS

Congenital erythropoietic porphyria (4)*
Porphyria cutanea tarda (5)†
Hepatoerythropoietic porphyria (5)*
Erythropoietic protoporphyria (8)*
X-linked erythropoietic protoporphyria (1)*

NEUROVISCERAL SYMPTOMS

Aminolevulinate dehydratase porphyria (2)*
Acute intermittent porphyria (3)‡

PHOTOSENSITIVITY AND NEUROVISCERAL SYMPTOMS

Hereditary coproporphyria (6)‡
Variegate porphyria (7)‡
Numbers in parentheses designate the enzyme defect responsible for the disorder (see Fig. 12-2)

*Clinical manifestations usually recognized in childhood.
†Clinical manifestations rarely recognized in childhood.
‡Clinical manifestations rarely occur before puberty except in children with homozygous or compound heterozygous genotypes.

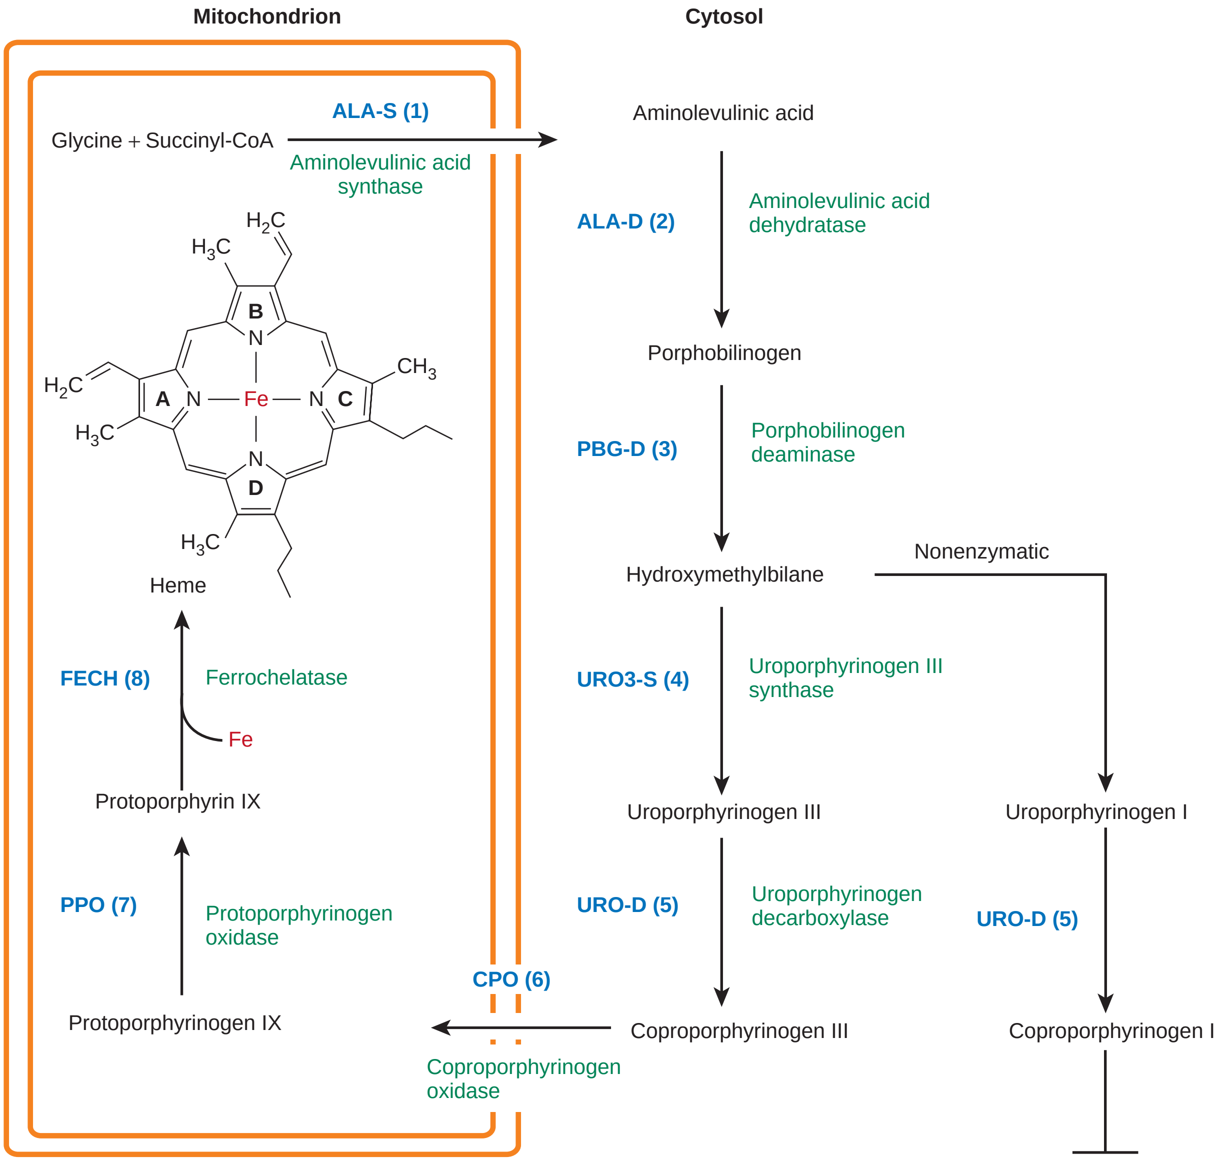
FORMATION OF THE PYRROLE

The δ-Aminolevulinate Synthases

Regulatory mechanisms controlling heme synthesis in erythroid precursors and in the liver differ. In the liver, heme biosynthesis must respond rapidly to changing metabolic requirements. In erythroid cells, the pathway is regulated to permit a high steady state level of heme synthesis, and regulation is tied to the availability of iron. The first and rate-limiting enzyme in the pathway in all cells condenses glycine and succinyl-coenzyme A to yield ALA (Fig. 12-3). This highly exergonic reaction occurs in the mitochondrial matrix and involves cleavage of the thioester bond of succinyl-coenzyme A. Two ALA-synthase (ALA-S) enzymes have evolved to accommodate the requirements of the liver (and other tissues) and the unique demands of the erythron. The first, ALA-S1, is expressed ubiquitously but at very low levels in erythroid precursors. The dominant form of ALA-S in erythroid cells is ALA-S2. The gene encoding ALA-S1 maps to the short arm of chromosome 3,[3] whereas ALA-S2 is encoded on the X-chromosome.[4] The two forms of ALA-S are 62% identical at the amino acid level.[5] Although these two forms of ALA-S are regulated differently, both forms require pyridoxal-phosphate (PLP) as a cofactor. Pyridoxine deficiency is therefore associated with hypochromic anemia.[6] Both ALA synthases function as homodimers.

ALA-Ss are highly conserved between species, and the crystal structure of a bacterial ALA-S (from *Rhodobacter capsulatus*) has been determined (Fig. 12-4).[7] The crystal structure supports the enzyme mechanism that had been suggested by biochemical studies.[8]

In eukaryotes, both forms of ALA-S are synthesized in the cytosol and then translocated to the mitochondrial matrix, the site of succinyl-coenzyme A generation by the tricarboxylic acid cycle. Both forms contain an amino-terminal mitochondrial targeting sequence that also contains heme-binding domains designated as heme regulatory motifs (HRM).[9] Binding of heme to the HRM inhibits mitochondrial import of both forms of ALA-S,



Mitochondrion
Cytosol
Glycine + Succinyl-CoA
ALA-S (1)
Aminolevulinic acid synthase
Aminolevulinic acid
ALA-D (2)

Figure 12-2 Heme biosynthetic pathway. The eight enzymes required to synthesize heme are named *(green)*. Abbreviations used throughout this chapter are in *blue*. Synthesis starts in mitochondria, depicted by the *double orange line*, continues in the cytosol, and terminates in mitochondria. Enzyme 6, coproporphyrinogen oxidase, is located in the mitochondrial intermembrane space. Enzyme 7, protoporphyrinogen oxidase, is an integral membrane protein associated with the inner membrane. Enzyme 8, ferrochelatase, an integral membrane protein, is located on the matrix side of the inner mitochondrial membrane.

TABLE 12-1 Diseases Linked to Steps in Heme Biosynthesis, Causative Genes, Chromosomal Locations, and Protein Codes

Disease	Gene	Location	OMIM	E.C. #	PDB
None	ALA-S1	3p21.1	125290	2.3.1.37	2BWN*
X-Linked Sideroblastic Anemia, X-Linked EPP	ALA-S2	Xp11.21	301300	2.3.1.37	
ALA-D Deficiency Porphyria	ALA-D	9q34	125270	4.2.1.24	1PV8
Acute Intermittent Porphyria	PBG-D	11q23.3	609806	4.3.1.8	3ECR
Congenital Erythropoietic Porphyria	URO3-S	10q25.2	263700	4.2.1.75	1JR2
Porphyria Cutanea Tarda, Familial Hepatoerythropoietic Porphyria	URO-D	1p34	176100	4.1.1.37	1URO

*Structure of bacterial homologue.

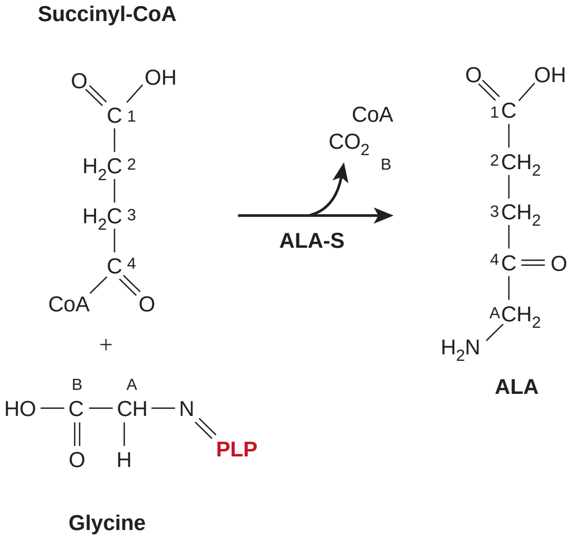

Figure 12-3 Synthesis of δ–aminolevulinic acid (ALA). In mitochondria, glycine is decarboxylated after forming a Schiff base with the cofactor pyridoxal phosphate (PLP). The reaction continues by condensation with succinyl-CoA, followed by release and recycling of CoA. The origin of the carbon atoms in ALA and CO_2 is indicated with either numbers or letters.

representing a posttranslational point of end-product feedback inhibition of the pathway.[10] The effect is greater for ALA-S1 than ALA-S2. In addition, developing erythroid cells express a heme transporter that prevents the accumulation of unbound heme in the cytosol (feline leukemia virus C receptor [FLVCR]).[11]

Both ALA-S1 and ALA-S2 are transcriptionally regulated but by quite different mechanisms. Extensive studies in avian embryonic liver cells indicated that hemin, a chloride salt of heme, repressed transcription of ALA-S1,[12] but the precise mechanism responsible for this effect has not been defined. Transcription of ALA-S1 is upregulated by the PGC-1α,[13] a coactivator of nuclear receptors and transcription factors.[14] Transcriptional regulation of ALA-S1 by PGC-1α is mediated by interaction of nuclear regulatory factor 1 (Nrf-1) and FOXO-1 (a forkhead family member) with the ALA-S1 promoter.[15] When cellular glucose levels are low, transcription of PGC-1α is upregulated,[16] leading to increased levels of ALA-S1 and creating conditions capable of precipitating acute attacks of the neurovisceral porphyrias. Upregulation of PGC-1α likely explains the clinical observation that fasting may precipitate attacks whereas glucose infusions are useful therapeutically.[17,18]

There are two splice forms of ALA-S1 in humans. The major form lacks exon 1B (Fig. 12-5) and is destabilized by heme.[19] The minor form includes exon 1B and is resistant to heme-mediated destabilization.[20] It is apparent that heme regulates ALA-S1 by multiple mechanisms, including transcription, translation, and translocation of the protein from the cytosol to the mitochondria. The regulatory effects of heme are mediated by the concentration of heme in small "pools" of heme not bound to hemoproteins.[21] Factors depleting unbound heme pools result in induction of ALA-S1, an effect that is the prime factor in precipitating acute attacks of the neurovisceral porphyrias.[22] No disease-causing mutations of ALA-S1 have been identified in humans, but down-regulating ALA-S1 with infusion of glucose and/or hemin forms the basis of therapy for acute porphyric attacks.[17,23]

In contrast to ALA-S1, ALA-S2 is transcriptionally regulated by erythroid specific factors (including GATA1) that interact with promoter sequences found in many genes differentially regulated in red cells.[24] Translational regulation also plays a major role in regulating expression of ALA-S2. The ALA-S2 transcript contains a 5' iron responsive element (IRE), which interacts with an IRE-binding protein (IRP).[25] The IRE-IRP complex prevents translation of the ALA-S2 mRNA. Addition of an iron-sulfur cluster (Fe/S) to IRP1 changes the conformation of the protein, reducing its affinity for the IRE. Fe/S clusters are generated and exported by mitochondria, linking regulation of heme biosynthesis in the red cell to the availability of iron and mitochondrial function.[26] Loss-of-function mutations in ALA-S2 are causative for

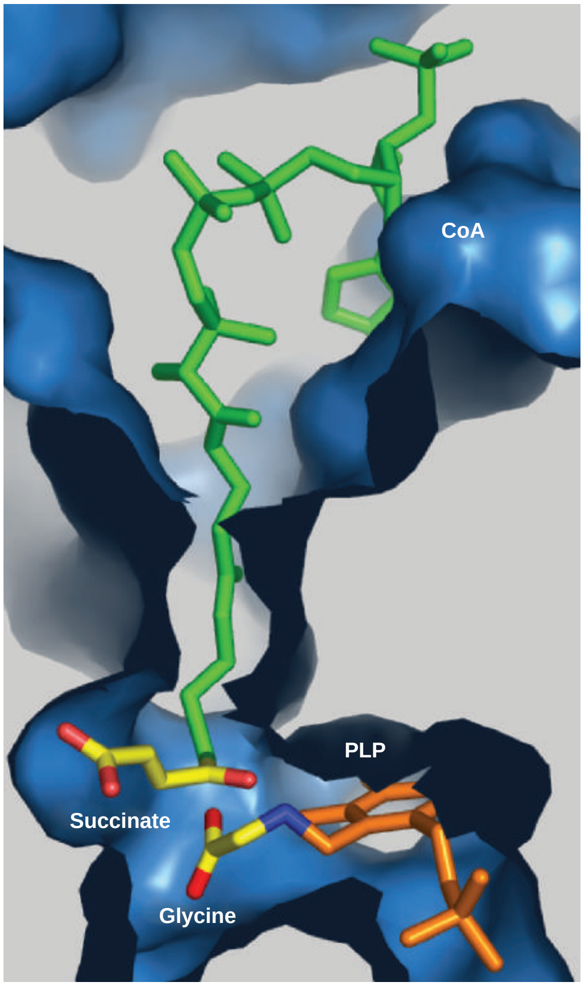

Figure 12-4 The active site of δ-aminolevulinate synthase (ALA-S) from ***Rhodobacter capsulatus***. Pyridoxal phosphate (PLP) *(orange)* forms a covalent linkage with a lysine residue. Glycine is bound through a transient Schiff base with PLP. Condensation with the succinate moiety of succinyl CoA, *(CoA in green)* allows the release of CoA, ALA, and PLP. The PLP cofactor is then bound again for subsequent rounds of catalysis.

Figure 12-5 Genomic organization of the promoters for early steps in heme synthesis. Chromosomal location for the gene *(Chr.)*. Two distinct genes encode δ-aminolevulinate synthase (ALA-S), a housekeeping form (ALA-S1) and an erythroid-specific form (ALA-S2). An iron responsive element (IRE) in exon 1 of ALA-S2 controls posttranscriptional gene expression. The next three genes utilize specific promoters for erythroid *(E)* or nonerythroid tissues *(H)*. The ATG start sites are designated *C*, common; *E*, erythroid; or *H*, housekeeping.

X-linked sideroblastic anemia (see Chapter 11). Gain-of-function mutations in ALA-S2 have been recognized as causative for X-linked erythropoietic protoporphyria (EPP) (see later discussion).[27]

δ-Aminolevulinate Dehydratase

Once synthesized, ALA exits mitochondria by an unknown mechanism likely involving a transporter. In the cytosol, two molecules of ALA undergo a condensation reaction catalyzed by δ-aminolevulinate dehydratase (ALA-D) (also known as *PBG synthase*) to form the monopyrrole PBG (Fig. 12-6). The crystal structure of human ALA-D and ALA-Ds from many other species indicate that the enzyme functions as a tetramer of homodimers formed from eight identical subunits.[28] Each of the homodimers contains one active site.[28] Each of the eight subunits binds a zinc atom, and the enzyme is inactivated by replacement of the zinc by lead. Four zinc

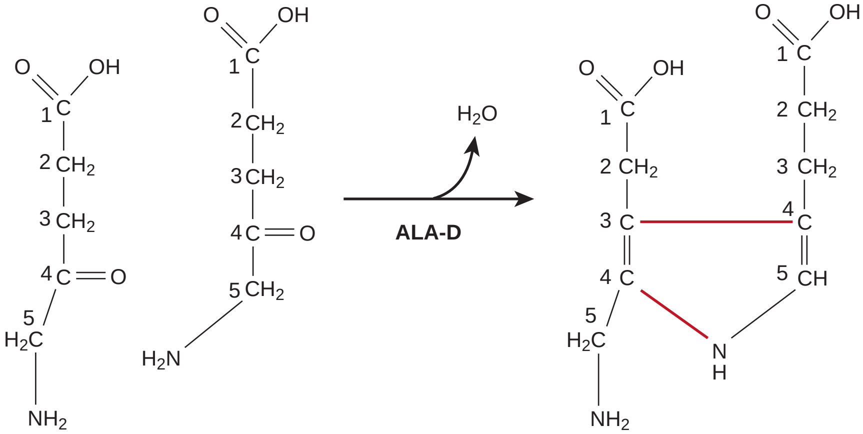

Figure 12-6 Reaction catalyzed by δ-aminolevulinic acid dehydratase (ALA-D). In the cytosol, two molecules of δ-aminolevulinic acid (ALA) condense to form porphobilinogen. The carbon atoms of each molecule of ALA are numbered for reference.

molecules are essential for catalysis. The remaining four zincs serve to stabilize the tertiary structure of the enzyme.[28] Each active site binds two molecules of ALA through the formation of Schiff base linkages with active site lysine residues, one for each of the two substrate molecules. One molecule of ALA contributes the acetate side chain and the aminomethyl groups of PBG. The other contributes the propionate side chain and the pyrrole nitrogen (see Fig. 12-6).

In contrast to ALA-S, there is a single ALA-D gene located on chromosome 9q34 (see Table 12-1).[29] The gene consists of two alternatively spliced noncoding exons (1A and 1B) and 11 coding exons (see Fig. 12-5).[30] The translational start site is located in exon 2. A housekeeping promoter is located upstream of exon 1A, and a second erythroid-specific promoter is located between exons 1A and 1B. The erythroid promoter contains binding sites for erythroid specific transcription factors including GATA1 and Krüppel-like factor 1.[31] Although the housekeeping and erythroid transcripts differ, they both encode identical proteins because they share the same translational start site in exon 2.

A common polymorphism of ALA-D, K59N, has been detected in approximately 10% of Caucasians, 3% of African Americans, and 6% to 11% of Asians.[32] This polymorphism has been designated the ALA-D2 allele. The ALA-D2 allele retains normal enzyme activity and appears to have a higher affinity for both zinc and lead than the ALA-D1 allele.[33] Lead-entering plasma is rapidly taken up by red cells and binds to ALA-D by displacing zinc and inactivating the enzyme.[34] Multiple studies have shown an association between the ALA-D2 allele and high blood lead levels,[33] but it remains unclear whether or not this allele is associated with increased susceptibility or increased resistance to lead toxicity.[34]

Although the quaternary structure of human ALA-D is that of a homo-octamer, a homo-hexamer form of ALA-D composed of three homodimers has also been detected. The homo-hexamer has low enzyme activity. The octameric and hexameric forms of ALA-D are described as morpheeins, indicating that dissociation of the high activity octamer is followed by a conformational change and then reassembly as the structurally different low-activity hexamer.[35] Conformational changes in the component dimers may result from substrate binding, but the most dramatic effects result from ALA-D mutations causative for ∂-aminolevulinate dehydratase deficiency porphyria (see later).[36]

In all tissues, the enzymatic activity of ALA-D greatly exceeds the activity of ALA-S. The abundance of ALA-D in comparison with all of the heme biosynthetic enzymes has been ascribed to the finding that ALA-D plays several roles, serving as a proteasome inhibitor affecting the ATP/ubiquitin-dependent degradation of proteins, playing a role in chaperone assisted protein folding, and as a heme biosynthetic pathway enzyme.[37,38]

δ-Aminolevulinate Dehydratase Deficiency Porphyria

ALA-D deficiency porphyria (ADP) is caused by homozygosity or compound heterozygosity for mutations of the ALA-D gene.

Frequency. ADP is an autosomal recessive disorder resulting from loss of function mutations of ALA-D. The disorder is exceedingly rare, and fewer than 10 cases have been reported, two in one family.[39] Most of the cases have represented compound heterozygotes. Eleven disease causing ALA-D mutations have been described, 10 of which are point mutations leading to amino acid substitutions.[40,41] The sole exception is the deletion of two sequential bases resulting in a frame shift yielding a premature stop codon.[42] Estimates of the frequency of heterozygosity for loss-of-function alleles of ALA-D, based on half-normal or less enzyme activity in erythrocytes of asymptomatic northern Europeans range from 1% to 2%.[43,44] The extreme rarity of homozygosity or compound heterozygosity for ALA-D mutations suggests a high incidence of embryonic lethality when two mutant alleles of ALA-D are present.

Clinical Manifestations. The clinical manifestations of ADP resemble those of the neurovisceral porphyrias but vary greatly in severity. The first two cases reported by Doss and colleagues in Germany were unrelated 15-year-old boys.[45,46] Both suffered recurrent attacks of abdominal pain, nausea, vomiting, constipation, tachycardia, and a motor neuropathy causing paralysis. A third German case reported by Doss and colleagues[47] also developed symptoms at age 15, including abdominal pain and a severe polyneuropathy. All three German patients were compound heterozygotes for ALA-D mutations.

The youngest reported case of ADP was a Swedish boy in whom muscle hypotonia was recognized at birth. At the age of 3, he developed recurrent attacks of abdominal pain, vomiting, and a motor polyneuropathy. This child also proved to be a compound heterozygote for ALA-D mutations.[48] A liver transplant was performed at the age of 6 with the assumption that the metabolic defect was most profound in the liver.[49] No change in the excretion of ALA was observed after the transplant, strongly suggesting that the red cells were the major source of this porphyrin precursor. The child died at the age of 9 of pneumonia and respiratory deficiency.[50]

The oldest reported case of ADP was a Belgian man who developed a motor neuropathy and markedly increased urinary ALA excretion at the age of 63.[51] ALA-D activity in erythrocytes was dramatically reduced to 1% of normal controls. The syndrome developed together with a clonal myeloproliferative disorder, namely polycythemia vera. Molecular studies revealed heterozygosity for a loss-of-function mutation (G133R) present in the polycythemia clone, which became clinically manifest with clonal expansion.[52] This represents the only case in which a fully penetrant phenotype occurred in a heterozygote and supports the suggestion that the source of excess ALA in ALA-D porphyria is the erythron.

In two other cases, partial biochemical evidence of ALA-D deficiency were detected in heterozygotes but by a completely different mechanism. The first was a healthy Swedish newborn undergoing neonatal screening for hereditary tyrosinemia.[53] Erythrocyte ALA-D activity was 12% of normal, and there were slight elevations of urinary ALA and coproporphyrin, as well as an increase in erythrocyte protoporphyrin. The child proved to be heterozygous for an F12L mutation, a catalytically inactive mutant that also affects secondary structure of the protein that favors formation of (with wild type protein) the low activity hexameric form of ALA-D.[35,41] In spite of the ALA-D defect, the child remained healthy and developed normally.

The second case of partial biochemical expression in a heterozygote ALA-D mutant occurred in a 23-year-old American man and was also due to the F12L mutation.[54] This patient presented with an acute porphyric attack clinically and biochemically compatible with hereditary coproporphyria (HCP). Indeed, a mutation of coproporphyrinogen oxidase (CPO) was identified. Because of a greater than usual increase in urinary ALA excretion and an increase in erythrocyte zinc protoporphyrin, an additional defect in ALA-D was suspected. Subnormal erythrocyte ALA-D activity was detected, and molecular studies revealed heterozygosity for the F12L mutation.

Pathogenesis. The pathogenesis of the symptom complex associated with ADP is poorly understood. It has been suggested that ALA may act as a neurotoxin based on structural similarities between ALA and glutamate and ALA and γ-aminobutyric acid (GABA).[55] High concentrations of ALA may interact with GABA receptors or inhibit glutamate uptake. ALA has been demonstrated to bind to GABA receptors in vitro, and GABA receptors are highly expressed by oligodendrocytes.[56] In addition, oligodendrocytes are highly sensitive to glutamate-dependent metabolic pathways, which could be impaired by the effect of ALA on glutamate uptake.[57] A possible role for ALA as a neurotoxin is supported in patients with hereditary tyrosinemia, who develop neurovisceral symptoms associated with marked inhibition of ALA-D by succinylacetone.[58]

Laboratory Diagnosis. Although ADP is rare, it should be suspected when an acute attack of abdominal pain suggests the possibility of a porphyric attack, especially when a prominent distal motor neuropathy is present. The dramatic reduction of ALA-D activity (to levels of 5% or less) results in the urinary excretion of large amounts of ALA and normal or minimally increased levels of PBG, a finding which distinguishes ADP from other neurovisceral porphyrias. Urinary excretion of coproporphyrin is markedly increased. The mechanism responsible for the increase in urinary coproporphyrin excretion is not known, but similar findings occur when ALA-D is inhibited in lead poisoning and when ALA is administered orally to normal individuals.[59] Zinc-protoporphyrin accumulates in erythrocytes in patients with ADP, again by a poorly understood mechanism.

Heterozygous parents and siblings of probands with ADP have approximately half-normal ALA-D activity as measured in red cell lysates. Erythrocyte ALA-D assays are available in reference laboratories in the United States and Europe. Gene sequencing is available for ALA-D mutation analysis through the Department of Human Genetics at the Mount Sinai School of Medicine, New York, N.Y.

It is important to emphasize that ALA-D activity can be subnormal in disorders other than ADP. Patients with lead poisoning often develop clinical signs and symptoms similar to those found in patients with ADP and other neurovisceral porphyrias. Lead in plasma is taken up by red cells and inhibits ALA-D activity by displacing zinc atoms from the enzyme.[34] The result is excess ALA in blood and urine, excess urinary excretion of coproporphyrin, and accumulation of zinc protoporphyrin in erythrocytes, findings also associated with ADP. The abnormal accumulation and excretion of porphyrins may be due, in part, to inhibitory effects of lead on CPO and FECH[60] but is more likely due to disposition of the excess ALA, as occurs in ADP. Lead poisoning can be distinguished from ADP by measuring the blood lead level.

Patients with hepatorenal tyrosinemia type I, an autosomal recessive disorder due to deficiency of fumarylacetoacetate hydrolase (FAH), manifest acute episodes of porphyric-like neurologic crises and secrete large amounts of ALA in the urine.[61,62] The FAH defect results in the generation of succinylacetone, a structural analog of ALA and a potent inhibitor of ALA-D.[63]

A single patient with an acquired reversible, unidentified inhibitor of ALA-D, high urinary ALA levels, and a porphyria-like acute attack has been reported.[64] In addition, both styrene and bromobenzene have been shown to inhibit ALA-D in rats.[65,66] Humans exposed to these compounds have moderately decreased erythrocyte ALA-D activity but do not suffer clinical consequences.

ADP is a rare disorder and must be differentiated from other causes of ALA-D deficiency. Biochemical and molecular evidence is essential to establish the diagnosis of ADP.

Treatment. Clear recommendations for the treatment of ADP are difficult because the number of reported cases is small, and the results of therapy have been variable. Suppression of ALA-S1 by the infusion of heme (heme arginate) proved effective in three German cases (all adolescent males),[46,47] and infusions of glucose, narcotic analgesics, and hemin were effective in a 14-year-old American boy.[40] Hemin infusion proved ineffective in the Swedish infant previously described.[48] There have been no reports of marrow transplantation in a patient with ADP. Avoidance of drugs known to induce acute attacks in other neurovisceral porphyrias, generally by depleting hepatic heme pools and inducing ALA-S1, is suggested but has not been proven to be useful.

ASSEMBLY OF THE TETRAPYRROLE

Porphobilinogen Deaminase

A polymer of four molecules of PBG is generated by PBG deaminase (PBG-D) (also called *hydroxymethylbilane synthase*), a cytosolic enzyme. The polymer, an unstable tetrapyrrole, is designated hydroxymethylbilane (HMB) (Fig. 12-7). PBG-D functions as a monomer, and the crystal structure of the human enzyme has been determined.[67] Purification of PBG-D from both mammals and bacteria has yielded an enzyme with a dipyrrole (dipyrromethane) in the active site. The dipyrrole serves as a

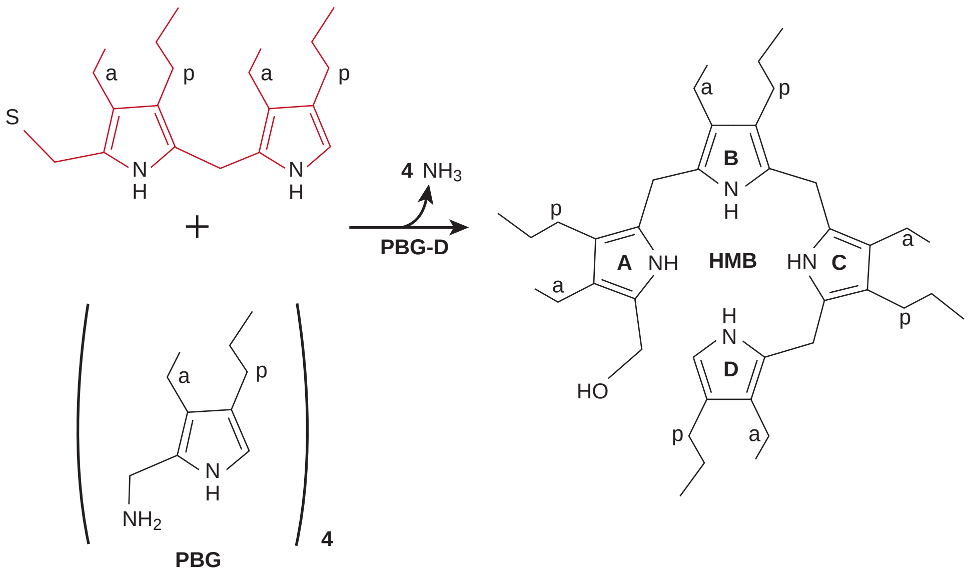

Figure 12-7 Reaction catalyzed by porphobilinogen deaminase (PBG-D). A dipyrrole cofactor, dipyrromethane *(red),* is covalently linked to the enzyme via a thioester bond. Four molecules of PBG are added, each releasing an amino group. Once a hexapyrrole has been formed, the terminal tetrapyrrole is cleaved and released as hydroxymethylbilane (HMB). The acetate *(a)* and propionate *(p)* side chains of the monopyrroles are labeled.

cofactor and is required for enzyme activity. A novel mechanism has been proposed to explain how PBG-D acquires the dipyrrole.[68] PBG-D first binds HMB and then deaminates and polymerizes two additional molecules of PBG to form a hexapyrrole. The distal tetrapyrrole is cleaved and released as HMB. The proximal dipyrrole remains covalently bound through a thioester linkage and serves as the cofactor for subsequent rounds of catalysis.[69] The source of the first HMB molecule to bind to PBG-D remains unexplained. Polymers of PBG can be formed nonenzymatically,[70] but incubation of apo-PBG-D with PBG yields very little holoenzyme with the dipyrrole cofactor bound.[71] It seems likely that the sequence of events involves nonenzymatic condensation of four molecules of PBG to form the amino-methylbilane, which interact with PBG-D. Although a poor substrate, amino-methylbilane is deaminated to form HMB, which is capable of forming a covalent thioester bond with PBG-D, leading to assembly of the initial hexapyrrole.[68]

The human PBG-D gene has been cloned and mapped to chromosome 11q23-11qter.[72,73] The gene spans 10 Kb and contains 15 exons.[74] Two separate promoters control transcription and allow tissue specific regulation of gene expression, a mechanism also used by ALA-D and URO3-S (see Fig. 12-5). The housekeeping promoter lies upstream of exon 1 and is active in all tissues. The erythroid-specific promoter lies upstream of exon 2 and resembles other erythroid-specific promoters.[75] Processing of the transcript initiated by the housekeeping promoter results in splicing of exon 1 to exon 3 and loss of exon 2. Transcription initiated by the erythroid promoter results in a transcript containing exons 2 through 15. Translation of the erythroid mRNA is initiated at an AUG located in exon 3, as exon 2 lacks an AUG codon.[74] The AUG translational start codon in exon 1 of the housekeeping transcript is spliced in frame with the AUG in exon 3, resulting in a protein 17 amino acids longer at the amino terminus compared to the erythroid protein.[76]

Acute Intermittent Porphyria

Acute intermittent porphyria (AIP) is caused by mutations of the PBG-D gene. Over 385 PBG-D mutations have been described.[77] The spectrum of mutations includes point mutations, deletions, duplications, and insertions and has been found in the housekeeping promoter, exons 1 and 3 through 15, and in each of the 14 introns. Exon 12 appears to be a mutational hot spot with 46 identified mutations.[78]

Frequency. AIP is transmitted as an autosomal dominant trait, but five symptomatic children homozygous for disease–causing PBG-D mutations have been reported.[55,79] Symptoms in these children began in infancy and included ataxia, dysarthria, psychomotor delay, and both central and peripheral neurologic manifestations. AIP is the most common of the acute neurovisceral porphyrias, but estimates of incidence vary according to the screening method used (clinical manifestations, erythrocyte PBG-D assays, molecular methods). Estimates based on a clinical diagnosis suggest an incidence of 0.13 per 1,000,000 in Europe.[80] The incidence in Sweden is approximately four times higher, [80] mainly due to a founder effect in northern Sweden.[81] When subnormal erythrocyte PBG-D activity is used for screening, the incidence of AIP in European populations is much higher,[82,83] but estimates based on erythrocyte PBG-D activity must be interpreted with caution. The normal range is wide, with considerable overlap between low-normal and high activity carrier values. Additionally, improper sample processing, storing, and shipping leads to decreased enzymatic activity.[17] Molecular screening for PBG-D mutations on a large scale in a general population has not been done. It is likely that the incidence of undetected gene carriers in the population is much higher than the incidence of clinically evident AIP because most gene carriers remain symptom free throughout their lives.[80] Recent estimates suggest a penetrance of only 1%.[84] In all series, clinical symptoms occur more commonly in women than men.

Clinical Manifestations. Clinical manifestations of AIP may occur before puberty in homozygotes or compound heterozygotes for PBG-D mutations, but most cases occur after puberty.[85-87] Pediatricians are likely to encounter adolescent patients with symptomatic AIP, particularly adolescent girls following menarche. Virtually all of the clinical signs and symptoms that characterize attacks of AIP are due to neurovisceral dysfunction (Table 12-2). Diffuse abdominal pain, often accompanied by nausea, vomiting, abdominal distention, and constipation, is the most common symptom of the acute attack.[17,88] Abdominal pain is usually unremitting and severe but occasionally may be cramping. Decreased bowel sounds and even signs of ileus are generally present, but some attacks may be associated with enhanced gut motility and diarrhea. Tachycardia is often present.[89] Other symptoms due to sympathetic over-activity or autonomic neuropathy include hypertension, tremors, sweating, and restlessness. Anxiety is a particularly common symptom, both during acute attacks and between attacks.[90] A variety of other neuropsychiatric symptoms associated with AIP have been described, ranging from hypomania to overt psychotic behavior,[91,92] and psychiatric symptoms may be the only manifestation of biochemically evident AIP.[93,94]

TABLE 12-2 Signs and Symptoms of the Acute Porphyric Attack

Signs and Symptoms	Frequency*	Comments
Gastrointestinal		
Abdominal pain	Common	Generally constant and not localized
Nausea and vomiting	Common	Accompanies abdominal pain
Constipation	Common	Urinary retention may occur also.
Diarrhea	Uncommon	
Neurologic		
Pain in back, chest, neck, head, extremities	Occasional	Pain may migrate to abdomen; may be accompanied by a sensory neuropathy
Paresis	Common	More proximal than distal; arms involved more often than legs
Respiratory paralysis	Uncommon	Occurs with progressive motor neuropathy and paresis
Mental symptoms	Occasional	Ranges from agitation to psychosis
Convulsions	Uncommon	Mainly occurs with hyponatremia
Cardiovascular		
Tachycardia	Common	Rate control with β-blockers may be needed.
Systemic arterial hypertension	Occasional	May become chronic and affect renal function

*Common: greater than 61%; Occasional: 21%-60%; Uncommon: less than 20%

A peripheral neuropathy may occur with or without an acute attack of abdominal pain. The neuropathy, due to axonal degeneration, is manifest mainly by muscle weakness in the extremities.[95] Nerve conduction abnormalities may be minor, even with symptomatic weakness, but sophisticated studies of slow motor fiber conduction have been abnormal, even in the absence of symptoms.[96,97] Cranial neuropathies are uncommon, but blindness due to optic nerve involvement or occipital lobe involvement has been reported.[98,99]

Seizures may occur during an acute attack and are often associated with hyponatremia.[100] When serum sodium levels are normal it is difficult to determine if the seizure is due to porphyria or to coexistent idiopathic epilepsy. In one large study of 268 patients, the lifetime prevalence of seizures was 5.1% in those who had suffered at least one acute attack and 2.2% in known carriers.[100] Seizures occurring during latent periods are likely to be related to AIP. It is essential to establish a firm diagnosis of idiopathic epilepsy in AIP patients who experience seizures because many antiseizure medications may precipitate acute attacks (see later; Table 12-3). If seizures are associated with the hyponatremia of an acute attack, prolonged antiseizure therapy is not necessary.

Hyponatremia is a common finding during acute attacks.[89] Hyponatremia maybe due to inappropriate secretion of antidiuretic hormone,[101] but renal salt wasting has been implicated in patients with the lowest serum sodium vales.[89] Serum sodium values below 120 nmol/L are generally found only in severe attacks.[102]

The likelihood of full recovery after an acute attack has increased dramatically over the last 25 years. This is undoubtedly due to the introduction of effective therapy with hemin or heme arginate (see "Treatment" section). The risk of death, however, has not been eliminated. A review of 136 patients hospitalized with acute attacks at the University of Minnesota between 1940 and 1998 (i.e., both before and after the introduction of hemin therapy) found that 29 (21%) had died during an acute attack.[103] In a study from Finland and Russia, 7 of 55 patients (13%) died as the result of an acute attack between 1966 and 2002. (Hematin therapy was first employed in 1971,[104] but not widely used until 1978.[105]) In another study of 47 Finnish patients ascertained between 1967 and 1989, 6 deaths (12.7%) occurred as the result of an acute attack.[106]

An unexplained finding in patients with AIP, variegate porphyria (VP), and HCP is a 35- to 70-fold increased risk of developing hepatocellular carcinoma. Most of these tumors occurred in individuals with a history of acute attacks. It has been suggested that DNA damage induced by ALA may be responsible for these observations.[107,108] An unusual feature of the hepatocellular carcinomas arising in porphyric patients is the absence of associated liver cirrhosis.[107,109] Chronic sustained hypertension is also prevalent in AIP and may be associated with renal impairment.[108]

Pathogenesis. Heterozygotes for PBG-D mutations have approximately half-normal enzyme activity in all tissues, which is usually sufficient for heme homeostasis. The enzymatic defect becomes manifest when demand for hepatic heme is increased, and ALA-S1 is induced. The result is increased production of ALA and PBG, creating a situation where the half-normal activity of PBG-D becomes rate limiting, and PBG (and ALA) accumulate in hepatocytes, circulate in plasma, and are excreted in the urine. Drugs are the most commonly recognized factors that increase the demand for hepatic heme, especially those metabolized by hemoprotein enzymes of the cytochrome P450 family.[22] Barbiturates, anticonvulsants, and steroid hormones are well recognized precipitating factors in patients with AIP, but other factors not directly connected with P450 metabolism have also been incriminated, including fasting, dieting, and the stress of an acute illness.[110,111] Most drugs taken by patients with AIP and other neurovisceral porphyrias have been classified as unsafe, potentially unsafe, probably safe, or safe. Isolated case reports have resulted in many drugs being classified as unsafe or potentially unsafe, resulting in a need for caution in drawing conclusions. Some drugs, however, have repeatedly been associated with acute porphyric attacks and must be avoided. A selection of these is shown in Table 12-3.

The current prevailing view is that symptoms of the porphyric attack result from the toxic effects of ALA and/or PBG rather than from a deficiency of heme in neurons.[55,112] The most striking evidence in support of this is the beneficial effect of allogeneic liver transplant in patients with repetitive and disabling acute attacks refractory to more conservative treatments.[113,114,115] An allogeneic liver transplant rapidly normalizes urinary excretion of ALA and PBG and eliminates recurrent neurovisceral attacks. Furthermore, when explanted livers from AIP patients were transplanted into nonporphyric patients, the recipients promptly developed biochemical and clinical evidence of AIP.[116] These impressive reports support the causative role of hepatic overproduction of ALA and PBG in acute neurovisceral attacks, but it is inappropriate to consider liver transplantation as a broadly applied treatment, especially with the efficiency of hemin or heme arginate infusions (see later).

TABLE 12-3 Selected Drugs Unsafe for Patients with Neurovisceral Porphyrias*

ACE inhibitors	Mephenytoin
Barbiturates	Metaclopramide
Carbamazepine	Primidone
Chlorpropamide	Progesterone
Danazol	Rifampin
Diphenylhydantoin	Succinimides
Ergots	Sulfasalazine
Estrogens	Sulfonamides
Glutethimide	Sulfonylureas
Griseofulvin	Valproic acid

*A complete list of unsafe and safe drugs is available at two websites: (1) www.porphyriafoundation.com and (2) http://www.porphyria-europe.com.

Laboratory Diagnosis. The signs and symptoms of an acute porphyric attack are quite nonspecific, and the correct diagnosis requires both consideration of a neurovisceral porphyria and a highly specific laboratory test. An acute porphyria is often not considered until fruitless, expensive imaging studies (and often unnecessary surgical exploration) are complete.

Increased urinary excretion of PBG is the key diagnostic finding in patients suffering an acute attack of AIP, HCP, or VP. Most methods used to quantify urinary PBG excretion rely on formation of a violet pigment when the sample is reacted with p-dimethyl aminobenzaldehyde (Ehrlich's aldehyde). Typical reference ranges for PBG excretion are 0-18 μmol/day (0 to 4 mg/day). Values for ALA range from 0 to 60 μmol/day (0 to 8 mg/day). In contrast, urinary PBG excretion during an acute attack generally range from 220 to 880 μmol/day, and ALA excretion ranges from 100 to 450 μmol/day.[17] Recently liquid chromatography-tandem mass spectroscopy methods have been developed that are rapid, specific, highly sensitive, and simultaneously measure ALA and PBG in urine and plasma.[117]

A simplified method for measuring PBG at the bedside or in the emergency department employs a small anion exchange column packed in a kit that includes all of the required reagents and a color chart. The trace PBG kit (Thermo Trace/DMA, Arlington, TX) can detect PBG at concentrations greater than 6 mg/L,[118] and results correlated well with standard quantitative assays.[119] The kit does not measure ALA.

Urinary porphyrin excretion (mainly uroporphyrin) is increased during acute attacks of AIP, mainly from nonenzymatic polymerization of PBG, but this is a much less specific finding than increased excretion of PBG and ALA. Fecal porphyrin levels are generally normal, but plasma levels may be increased. In contrast, increased urinary porphyrin excretion during an acute attack of HCP and VP consists mainly of coproporphyrin, and stool porphyrin excretion is also increased. Markedly increased stool coproporphyrin and protoporphyrin are found in VP. Fluorescence scanning of diluted plasma at neutral pH readily distinguishes VP from the other neurovisceral porphyrias, even during asymptomatic periods.[120]

A word of caution is required in interpreting urinary porphyrin values. Minimal elevations of urinary coproporphyrin may be found in patients with liver disease, marrow disorders, and a host of other illnesses. An incorrect diagnosis of porphyria is commonly made by overinterpreting minimal elevations of urinary coproporphyrin, leading to a delay in establishing the true cause of abdominal pain and other neurovisceral symptoms.

Assays of PBG-D activity in erythrocyte lysates have been widely employed to confirm the diagnosis of AIP and to detect asymptomatic family members once an index case has been identified. Erythrocyte PBG-D activity is approximately half-normal in most patients with PCT. Normal PBG-D activity, however, does not exclude a diagnosis of AIP because of differential splicing of the PBG-D transcript in the liver and the red cell. Mutations in exon 1 of the PBG-D gene affect activity of the enzyme in the liver, but the erythrocyte enzyme is encoded only by exons 2 through 15.[74] It is important to emphasize that a valid half-normal measurement of erythrocyte PBG-D activity does not distinguish between asymptomatic (latent) and clinically manifest cases of AIP. Only urinary PBG levels can make this distinction.

PBG-D mutation detection by DNA analysis has proven to be more reliable than PBG-D enzyme assays and is now the preferred method for confirming a diagnosis of AIP and for identifying asymptomatic carriers. DNA studies have demonstrated that enzymatic assays may misclassify up to 15% of individuals tested.[121,122] Mutation detection for AIP patients and their relatives is now readily available through the Department of Human Genetics at the Mount Sinai School of Medicine, New York, N.Y.

Treatment. Treatment of an acute attack of AIP (and the other neurovisceral porphyrias) is designed to repress the activity of hepatic ALA-S1 and to offer supportive care and relief of symptoms. Intravenous infusions of heme result in a rapid reduction in levels of ALA and PBG in plasma and urine.[17] Heme binds to plasma hemopexin and albumin and is then taken up by hepatocytes, where it expands the heme pool and represses ALA-S1. Many small, uncontrolled trials have demonstrated both biochemical and clinical responses to infusion of heme.[17] In one study involving 22 patients suffering 57 acute attacks, all patients responded favorably, but therapy was most beneficial when administered early in the attack,[123] a finding confirmed by others.[124,125] A single, placebo-controlled trial found dramatic biochemical benefits of heme infusion, but clinical benefits were more difficult to confirm.[126]

Heme is not soluble at neutral pH, but solubilized hemin (heme-chloride) and heme arginate have been administered to many patients. In the United States a lyophilized preparation of hemin, (Panhematin, Recordati Rare Diseases, Lebanon, NJ) has been approved by the U.S. Food and Drug Administration for the treatment of acute porphyric attacks. Hemin is unstable when reconstituted with sterile water, and degradation may cause an anticoagulant effect and phlebitis at the site of infusion.[127] Phlebitis can be avoided by the use of intravenous catheters that extend to larger veins (e.g., the superior vena cava). Instability and the locally irritating effects of lyophilized hemin can be attenuated by solubilizing hemin in 25% albumin, a method now recommended.[17] The recommended regimen for heme therapy is 3 to 4 mg/kg infused once daily on 4 consecutive days. Clinical improvement generally occurs within 1 or 2 days, but when neuronal damage is severe, complete recovery may take months. The keys to success are to initiate therapy as soon as an attack is recognized and to complete a 4-day course. Rare side effects of therapy include constitutional symptoms such as fever, myalgias, and malaise, but one case of marked hypotension[128] and another of transient renal failure[129] have been reported. The latter case was associated with an excessive dose (1000 mg) of hemin.

Heme arginate (Normosang, Orphan Pharmaceuticals, Paris, France) is more stable in solution than hemin, is equally effective, and is widely available in Europe and South Africa but remains an experimental drug in the United States. Phlebitis is a rare complication with heme arginate,[130] and the shelf life is considerably longer than that of hemin. Accidental overdosing with heme arginate has been associated with acute hepatic failure.[131] Adenoviral-mediated hepatic expression of PBG-D corrects the metabolic defect in mouse models of AIP,[132,133] but no studies have been done in humans. Intravenous infusions of recombinant human PBG-D have been administered to normal subjects and asymptomatic PBG-D mutation carriers.[134] Transient decreases in plasma concentrations of PBG were noted, and no serious side effects occurred. No trials of recombinant PBG-D for the treatment of symptomatic AIP have been reported.

Intravenous infusions of glucose (300 to 500 g/day, administered as 10% glucose) may be effective when an attack is mild or until hemin is obtained,[17] but glucose is far less effective than hemin. Infusions of glucose in water solutions are contraindicated because they aggravate hyponatremia, which can prove fatal.[135] The mechanism of the glucose effect relates to the previously described finding that transcription of ALA-S1 is upregulated by the peroxisome PGC-1α and transcription of PGC-1α is controlled by glucose availability.[13] Insulin may downregulate PGC-1α,[13] and it has been suggested that the combination of glucose and insulin may be more effective than glucose alone.[18]

Acute attacks require treatment of symptoms in addition to therapy directed at ALA-S1. Pain is often severe, and full doses of morphine or other opioids are both safe and effective. Phenothiazines in modest doses are safe and are useful for the control of nausea and anxiety.[17] Hypertension and tachycardia may respond to β-adrenergic blocking agents,[136] but these agents should be used with caution when patients are hypovolemic because increased catecholamine secretion is often an important compensatory mechanism. Seizures during an acute attack can be a particularly vexing problem because most antiseizure drugs have the potential to worsen the intensity of the attack.[137] Clonazepam and gabapentin may be safe,[138,139] and benzodiazepines are probably safe.[17] Hyponatremia and hypomagnesemia should be corrected because these abnormalities are common and may be causative for seizures.

The long-term management of patients with acute neurovisceral porphyrias is focused on the prevention of future attacks. Avoidance of unsafe drugs (see Table 12-3) is critical as is maintenance of a balanced, calorically adequate diet. In some women acute attacks occur only in the luteal phase of the menstrual cycle. In these cases gonadotropin-releasing hormone (GnRH) analogues can be highly effective.[140,141,142] Prolonged use of GnRH analogues in young women may cause irreversible bone loss, but low-dose transdermal estradiol may safely prevent this complication.[143,144] Both cyclic and noncyclic attacks may be prevented by frequent infusions of hemin,[17] but the expense and the potential for iron overload (8 mg of iron per 100 mg of hemin) makes this an unattractive option.

Levels of progesterone, an inducer of hepatic heme synthesis, are elevated in pregnancy, but pregnancy is well tolerated by most women with acute porphyrias.[106,145] In a large series reported from Finland of 176 pregnancies in women with AIP or VP, porphyric symptoms occurred in fewer than 10%.[106] Worsening symptoms during pregnancy may be due to harmful drugs,[146,147] inadequate nutrition, or both.[17]

Uroporphyrinogen III Synthase

The product of the PBG-D reaction, HMB, serves as the substrate for uroporphyrinogen III synthase (URO3-S). URO3-S catalyzes the asymmetrical cyclization of HMB to the III isomer of uroporphyrinogen (uro'gen III). The reaction involves "flipping" of the D ring to yield the asymmetric product (Fig. 12-8). Rearrangement of the D ring occurs by a complex mechanism involving cleavage and formation of carbon–carbon bonds.[148] Spontaneous cyclization of HMB can also occur, but the product, uroporphyrinogen I (uro'gen I), cannot ultimately be converted to heme. URO3-S functions as a monomer. Although the primary sequence is highly divergent, the crystal structures of human URO3-S and a bacterial URO3-S are nearly identical.[149,150] The structure of URO3-S from the bacterium *Thermus thermophilus* has been determined with the uro'gen III product bound.[150] The structure suggests that the enzyme prevents formation of uro'gen I by positioning the A and D rings to favor formation of uro'gen III.

The human URO3-S gene is localized to chromosome 10q25.2-26.3[151] (see Table 12-1) and contains 10 coding exons.[152] The translational start site is located in exon 2B (see Fig. 12-5). Both housekeeping and erythroid-specific transcripts are produced. The housekeeping promoter lies upstream of exon 1.[153] The housekeeping transcript results from a splicing event that joins exon 1 and 2B. The erythroid-specific promoter lies within intron 1 and contains eight GATA1 binding sites. The erythroid-specific transcript contains all of exon 2. Although the housekeeping and erythroid transcripts are expressed from different promoters, they produce identical proteins.

Congenital Erythropoietic Porphyria

Congenital erythropoietic porphyria (CEP) (Günther disease) is a rare form of porphyria in humans due to mutations of URO3-S. About 200 cases have been reported.[154] The disorder is of historical interest as it was the first porphyria to be recognized as an inherited trait and the first to be characterized biochemically.[155] CEP also occurs in squirrels, cows, and other species.[156] Over 40 URO3-S mutations have been reported, including exonic and promoter point mutations, deletions, insertions, and splice-site mutations.[157]

Frequency. The rarity of CEP makes frequency estimates difficult, but the disorder has been described in multiple ethnic groups.[158] The frequency of heterozygosity for URO3-S mutations is not known because heterozygotes have no phenotype, and population-based sequencing screens have not been done. Although rare, CEP is recognized more frequently than ALA-D porphyria, perhaps because of the dramatic cutaneous phenotype.

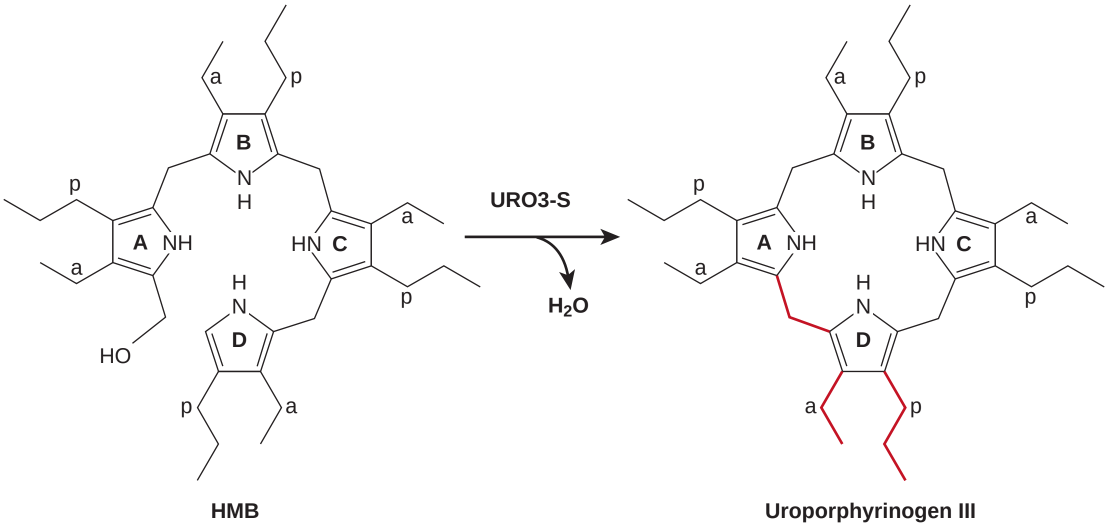

Figure 12-8 Reaction catalyzed by uroporphyrinogen III synthase (URO3-S). URO3-S enzymatically closes the tetrapyrrole ring with concomitant "flipping" of the D ring. The acetate *(a)* and propionate *(p)* side chains are labeled. In the uroporphyrinogen III product, the acetate and propionate groups of the D ring are reversed.

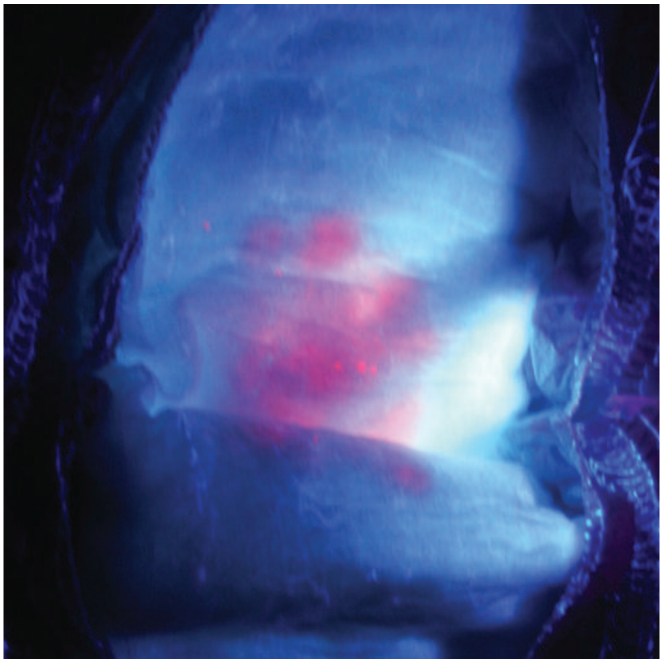

Figure 12-9 The diaper from a child with congenital erythropoietic porphyria. Urine porphyrins, primarily uroporphyrin I, fluoresce with a brilliant pink color when illuminated with a Wood's light.

Clinical Manifestations. Cutaneous photosensitivity is the most dramatic feature of CEP and is usually recognized in early infancy. The diagnosis may be suspected because of the dark brown color of urine soaked diapers that demonstrate a distinctive, intense red-pink fluorescence when illuminated with long-range ultraviolet light (e.g., a Wood's light) (Fig. 12-9).[154] The severity of the skin lesions varies widely and is related to the amount of residual URO3-S activity,[159] which in turn determines the magnitude of porphyrin accumulation and excretion. In most cases photosensitivity is severe and is characterized by skin fragility, bullous lesions, ulcerations, and secondary infections.[158] If exposure to sunlight is not rigorously avoided, mutilation of the face and hands is the ultimate outcome (Fig. 12-10). A common finding in CEP and the other porphyric disorders associated with photosensitivity is the presumably protective response of extensive hypertrichosis.[154,158] Photoinduced damage of nails and ocular structures may also occur.[158] A unique finding in children with CEP is red-brown discoloration of the teeth, due to deposition of porphyrins into dentine and enamel during tooth development.[160] The teeth fluoresce when illuminated with a Wood's light.

Hemolytic anemia of varying severity is found in nearly all cases, but detailed morphologic findings in the blood and bone marrow have been reported infrequently. Ineffective erythropoiesis may also be present. Poikilocytosis, nucleated red cells, and basophilic stippling are common, and the marrow demonstrates erythroid hyperplasia and may manifest marked dyserythropoiesis.[161-163] Fluorescence microscopy may demonstrate fluorocytes in the peripheral blood, but this is more dramatic in the bone marrow.[156,161,164] Splenomegaly generally accompanies the hemolytic anemia, and the magnitude of splenic enlargement reflects the severity of hemolysis. Transfusion dependence may develop.[154] Leukopenia and symptomatic thrombocytopenia may occur as a result of splenic sequestration.[165]

A variety of osteolytic skeletal lesions have been described when the disease reaches the stage of mutilation.[158] Vitamin D deficiency as a result of sun avoidance

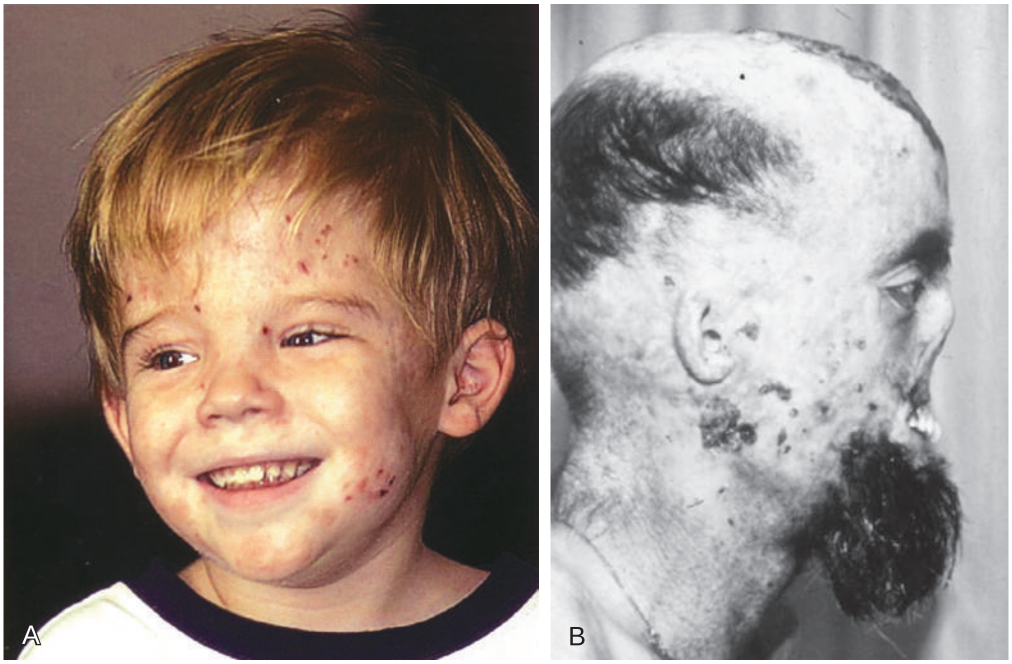

Figure 12-10 Skin changes in congenital erythropoietic porphyria (CEP). **A,** A 3-year-old boy with early facial photodermatitis. **B,** A severe case of CEP in an adult. Sun exposure has lead to blistering, erosions, secondary infections, and subsequent photomutilation.

may play a role in the development of osteolysis.[166] At postmortem examinations the skeleton is fluorescent under long-range ultraviolet light.[167]

Pathogenesis. Loss-of-function mutations of URO3-S lead to the accumulation of the HMB substrate in erythrocyte precursors, which is readily converted nonenzymatically to uro'gen I. Residual activity of URO3-S is generally less than 10% of normal. Uro'gen I may be auto-oxidized to uroporphyrin I or may serve as a substrate for uroporphyrinogen decarboxylase (URO-D) (Fig. 12-2), ultimately generating coproporphyrinogen I (copro'gen I). This results in a metabolic "dead end" as the next enzyme in the pathway, CPO, is stereospecific and will only accept coproporphyrinogen III (copro'gen III) as a substrate. Uroporphyrin I and to a lesser extent coproporphyrin I accumulate in erythroid precursors. Erythrocyte fragility and hemolysis result by an undefined mechanism, liberating porphyrins into the plasma. Uroporphyrin I mediates the cutaneous photosensitivity[168] and is excreted in the urine. Coproporphyrin I is excreted in the stool and to a lesser extent in the urine.

Two phenotypic copies of CEP have been reported. In one, a partial defect in URO-D combined with a congenital dyserythropoietic anemia produced mutilating photosensitivity and massive uroporphyrinuria.[169] The pattern of urinary porphyrin excretion differed from CEP as large amounts of heptacarboxyl porphyrin were found in addition to even larger amounts of uroporphyrin. In the other, a mutation in the erythroid specific transcription factor GATA1 resulted in subnormal URO3-S in red cells and a phenotype of CEP, thalassemia intermedia, and thrombocytopenia.[170]

The clinical manifestations of CEP vary greatly, but a unique case has been reported in which a gain-of-function mutation of ALA-S2 coexisted with compound heterozygosity for loss-of-function mutations of URO3-S.[171] The result was a severe CEP phenotype compared to other family members with the same URO3-S genotype.

Late Onset CEP. CEP may become evident in adult life, and clinical symptoms are generally less severe than in the more typical early-onset cases. In most of the adult-onset cases, moderate URO3-S defects became evident only when an acquired clonal marrow disorder developed.[172,173]

Laboratory Diagnosis. Urinary porphyrin excretion is massively increased in CEP, in some cases up to 1000 times normal. The pattern of porphyrin excretion, determined by high-performance liquid chromatography is characteristic. The dominant urine porphyrin is uroporphyrin I with smaller amounts of coproporphyrin I.[174,175] Assays of URO3-S have been performed in erythrocytes and cultured cells, but the assays are not widely available.[176,177] The most practical way to confirm the diagnosis of CEP is through direct sequencing of the gene, a procedure available through the Department of Human Genetics at the Mount Sinai School of Medicine in New York, N.Y. URO3-S mutations can be detected in chorionic villi or cultured amniotic cells.[178] This may be useful in subsequent pregnancies when parents have had a child with CEP.

Treatment. The only curative therapy for CEP is an allogeneic marrow transplant. Sixteen patients with CEP who have undergone allogeneic transplants have been reported.[179] The published experience suggests that early transplant is preferred, particularly when hematologic manifestations are prominent, but this approach is not universally applicable because of potential donor availability, treatment-related morbidity, and financial constraints. Allogeneic transplants should probably be restricted to the more severe cases of CEP because conservative management can yield longevity of 40 to 60 years.

The morbidity associated with marrow allografts could be avoided by autologous hematopoietic stem cell transplant if stem cells could be stably transfected with a normal URO3-S cDNA. This has been accomplished in a murine model of CEP using a lentivirus vector[180] and in isolated keratinocytes from a CEP-affected individual.[181] In the latter case, the lentiviral vector was excised, yielding induced pluripotent stem cells free of viral reprogramming genes. Complete correction of the phenotype was achieved in both the murine model and in the human pluripotent stem cells. No clinical trials in humans have yet been reported.

Avoidance of sunlight is at the core of conservative management.[179] This can be achieved with protective clothing and effective sunscreens. Conventional sunscreens containing para-aminobenzoic acid are ineffective and opaque "pancake" makeup is preferred. Splenectomy may reduce the severity of hemolysis and correct leukopenia and thrombocytopenia, but beneficial effects on photosensitivity are often transient.[182] Erythropoiesis and endogenous porphyrin production can be suppressed with aggressive transfusion regimens,[183] but transfusion-induced iron overload results.[184]

MODIFICATION OF THE TETRAPYRROLE SIDECHAINS

Uroporphyrinogen Decarboxylase

Uro'gen III is converted to copro'gen III by the sequential removal of the carboxyl groups of the four acetate side chains yielding four methyl groups. This reaction is catalyzed by the cytosolic enzyme URO-D (Fig. 12-11). Decarboxylation of uro'gen III begins at the asymmetric D ring and proceeds in a clockwise manner.[185] Uro'gen III is the preferred substrate. The enzyme will accept uro'gen I as a substrate, but the product, copro'gen I, cannot be converted to heme.

Human URO-D is encoded by a single gene located on chromosome 1p34 (see Table 12-1).[186] Unlike ALA-D, PBG-D, and URO3-S, there is no erythroid specific promoter in the URO-D gene.[187] The URO-D mRNA is highly expressed in developing erythrocytes, but the mechanism responsible for erythroid-specific upregulation is not known.[188]

URO-D has been purified from human erythrocytes,[189,190] bovine liver,[191] and from yeast and bacteria.[192]

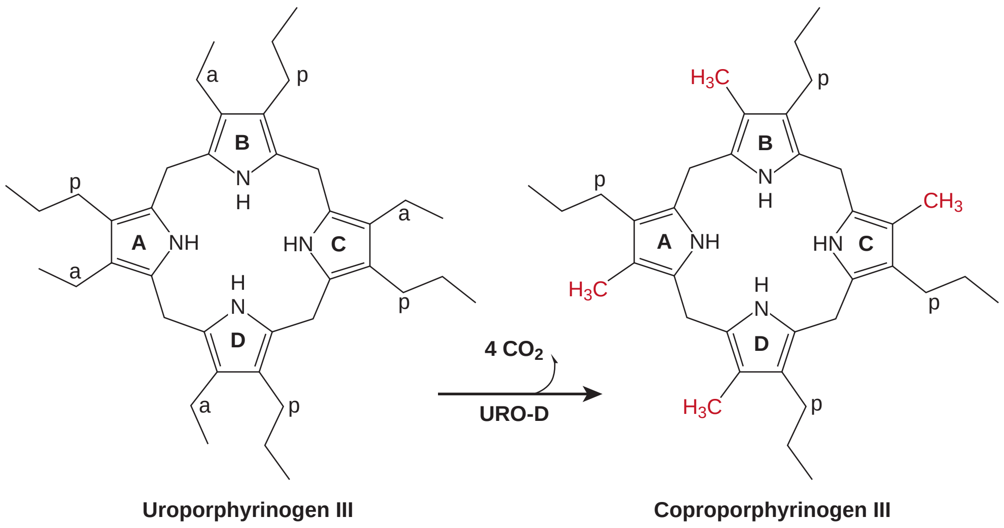

Figure 12-11 Reaction catalyzed by uroporphyrinogen decarboxylase (URO-D). Uroporphyrinogen undergoes four successive decarboxylations, starting at the asymmetric D ring. The acetates side chains *(a)* are decarboxylated to form methyl groups. URO-D will decarboxylate both the I and III isomers of uroporphyrinogen, but coproporphyrinogen I is not a substrate for coproporphyrinogen oxidase.

Unlike most decarboxylases, URO-D does not require cofactors or prosthetic groups for activity. The crystal structure of human URO-D has been determined, revealing that URO-D functions as a homodimer.[193,194] Each monomer contains an active site cleft. The active site can only accommodate the flexible porphyrinogen macrocycle (see Fig. 12-12).[195] Oxidation of the bridge carbons connecting the pyrrole rings renders the molecule rigid and planar and may explain why uroporphyrin is not a substrate for URO-D.

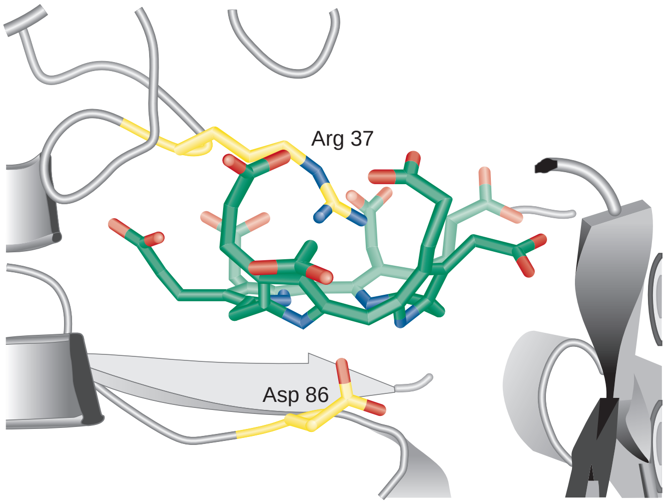

Figure 12-12 Crystal structure of uroporphyrinogen decarboxylase with uroporphyrinogen III (uro'gen III) bound in the active site. Uro'gen III *(green)* is shown in the active site. The fully reduced bridge carbons permit uroporphyrinogen to adopt the domed configuration positioning the 4-pyrrole nitrogens for hydrogen bonding with aspartic acid 86 *(Asp 86)*. The positive charge of arginine 37 *(Arg 37)* interacts with the negatively charged propionate groups of uroporphyrinogen to correctly position the substrate in the active site. *(Adapted from the coordinates 1R3Y, available from the Protein Data Bank.)*

Porphyria Cutanea Tarda

PCT is due to subnormal activity of URO-D in the liver. The disorder is characterized clinically by a photosensitive dermatosis that is usually less severe than in CEP. Expression of the clinical phenotype is associated with one or more risk factors: iron overload, often due to homozygosity for the C282Y mutation of the hemochromatosis gene (HFE); hepatitis C; alcohol abuse; and the use of medicinal estrogens.[196-198] The frequency of these risk factors is far higher than observed incidence of PCT, suggesting that susceptibility factors, either genetic or environmental, yet to be identified are important determinants of disease expression.[196,199]

Two major variants have been identified. The first, designated familial PCT (F-PCT), is associated with heterozygosity for mutations at the URO-D locus. F-PCT is transmitted as an autosomal dominant trait. Affected individuals display approximately half-normal URO-D activity and half-normal URO-D protein in all tissues.[200,201] There is considerable variation in URO-D activity because different mutations have varied effects on enzyme activity.[202] F-PCT accounts for approximately 25% of the clinically observed cases.[196,203] Most carriers of a mutant URO-D allele do not express a porphyric phenotype unless one or more of the risk factors mentioned above are also present.[196] Clinical expression of F-PCT in childhood is rare.[204-209] The authors have evaluated three children with F-PCT, two of whom were brothers, who were also homozygous for the C282Y HFE mutation.

The second major variant, and the most prevalent form of PCT, is designated sporadic PCT (S-PCT) and accounts for approximately 70% of cases.[196] In S-PCT, reduced activity of URO-D is restricted to the liver. No URO-D mutations have been identified in patients with S-PCT, and there is no evidence of a liver-specific URO-D transcript.[210] Nevertheless, S-PCT may cluster in families suggesting the presence of predisposing genetic factors.[211]

The concentration of URO-D protein is normal in all cells, including the hepatocytes, yet when the disease phenotype is expressed, enzyme activity is markedly reduced in the liver. Normal URO-D protein concentration coupled with subnormal URO-D enzymatic activity strongly suggests the presence of an enzyme inhibitor.[212-214] Risk factors identified when S-PCT is clinically evident are identical to those associated with F-PCT.[196,215]

A third rare variant of PCT occurs in children who have inherited two mutant alleles of URO-D.[215-219] This variant has been designated hepatoerythropoietic porphyria (HEP) because porphyrins accumulate in both the liver and the red cells. Severely reduced levels of URO-D resulting from the genetic defect become rate limiting. Activity in red cell lysates is generally less than 10% of normal[220] but may be as high as 20% in cases with a mild phenotype.[218]

A fourth variant of PCT, designated toxic PCT, has been associated with exposure to halogenated aromatic hydrocarbons. An epidemic of toxic PCT occurred in Turkey between 1956 and 1961 following ingestion of wheat treated with the fungicide hexachlorobenzene.[164,221] Many of the Turkish cases were children. Later studies in animals established that the halogenated aromatic hydrocarbons diminished hepatic URO-D activity.[222-226] PCT in humans has also been reported following exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD)[227,228] and dichlorophenols and trichlorophenols.[229]

Frequency. PCT is the most common of the porphyric disorders, but the incidence varies in different populations. In Caucasian populations of northern European origin, the incidence may be as high as 2 to 5 per 20,000, likely reflecting the high incidence of hemochromatosis gene mutations in this group.[196] In contrast, PCT is uncommon in African Americans but does occur in the Bantus of South Africa, who develop iron overload from beer brewed in iron pots.[230] PCT occurred commonly in patients undergoing chronic hemodialysis,[231-233] but substitution of erythropoietin for red cell transfusions (hence avoiding transfusion-induced iron overload) has reduced the incidence.

The high frequency of PCT, with one quarter of cases associated with URO-D mutations, predicts that HEP should not be rare. Instead fewer than 40 cases have been reported.[218] This is best explained by embryonic lethality of extremely low residual activity of mutant URO-D enzymes or the lethal effect of null alleles.

Clinical Manifestations. Skin fragility on the dorsal aspects of the hands is often the initial finding, but blistering lesions (bullae) then appear on all sun-exposed areas. The fluid-filled bullae rupture, and the denuded area heals slowly, often forming thick eschars and eventually hyperpigmented patches (Fig. 12-13). Facial hypertrichosis is common, particularly in children and women. Facial hypertrichosis may be localized to periorbital regions (Fig. 12-14*A*) or can be manifest in a lanugo-like diffuse facial pattern with or without pigmentation (Fig. 12-14*B*). Some patients develop scleroderma-like skin changes, mainly in light-exposed areas.[234,235] When PCT becomes

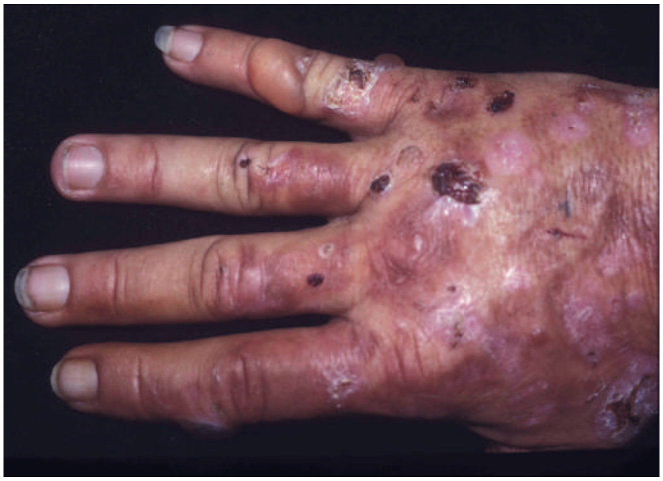

Figure 12-13 Hand of a patient with porphyria cutanea tarda. Bullous lesions form (note large blister on fifth digit) and rupture, leaving ulcerations that heal slowly. The resultant scars are both hypopigmented and hyperpigmented.

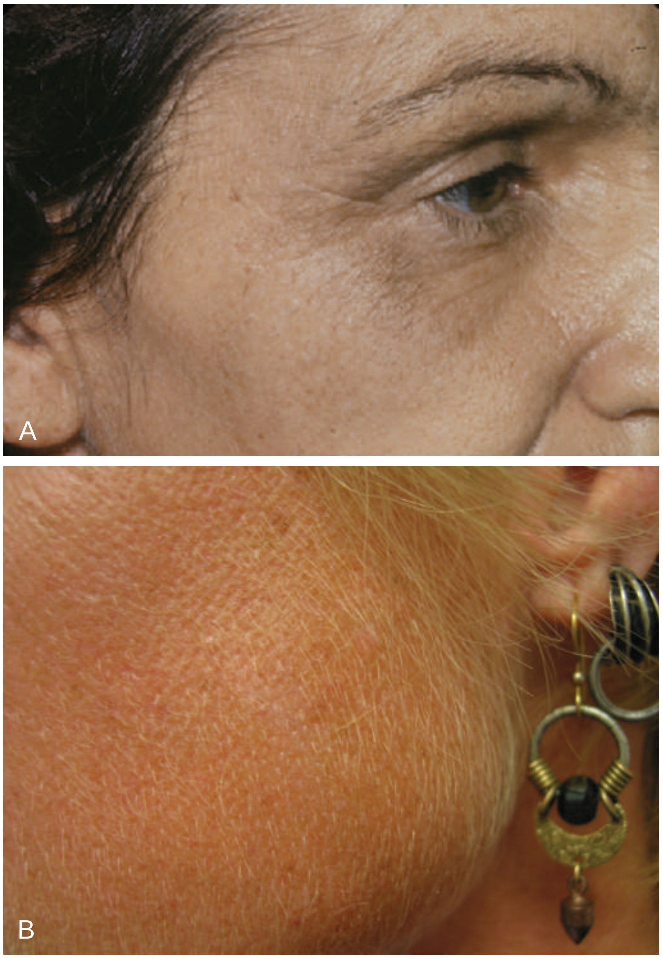

Figure 12-14 Facial hypertrichosis with porphyria cutanea tarda (PCT). **A,** Characteristic periorbital facial hair in a 60-year-old woman in whom PCT developed while receiving postmenopausal oral estrogen replacement. **B,** Diffuse lanugo-like facial hair in a 26-year-old woman in whom PCT developed while using an oral contraceptive.

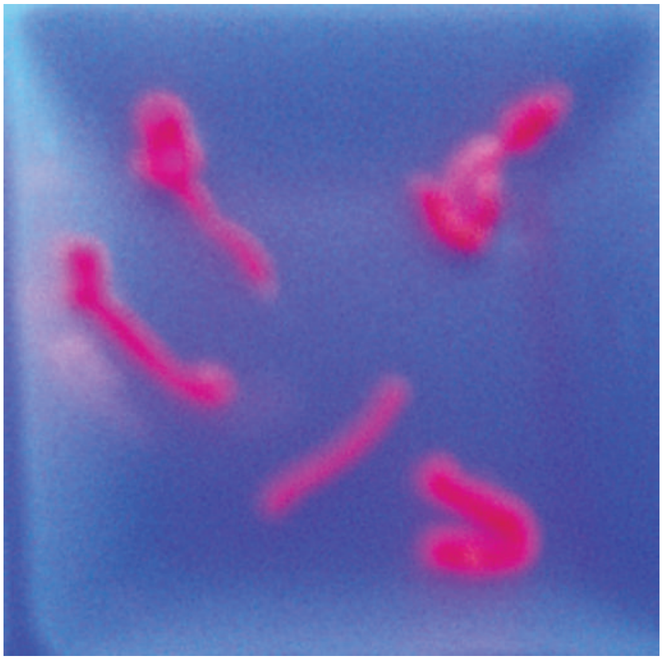

Figure 12-15 Percutaneous liver biopsy specimens from five patients with porphyria cutanea tarda. The massive amount of porphyrins in hepatocytes results in striking fluorescence under illumination with a Wood's light.

chronic, milia (small, cystlike collections of keratin) are common on the hands.[236] Similar photocutaneous findings have been seen in patients with pseudoporphyria, a disorder in which plasma and urine porphyrins are normal. The skin findings are likely due to other photosensitizing compounds. Nonsteroidal antiinflammatory drugs have been implicated in most cases.[237]

The cutaneous manifestations of HEP can be very dramatic and may resemble those seen in CEP.[238] Recurrent blisters and erosions complicated by infection can lead to severe scarring, scleroderma-like changes, and photomutilation.[85,220] In other cases the skin is less severely damaged and appears more like mild PCT.[239,240] Hemolytic anemia and splenomegaly may be present, findings not associated with PCT.[220]

Evidence of abnormal liver function is nearly always present in patients with PCT, even in those without hepatitis C. In some reports, approximately 80% of males with PCT have been infected with hepatitis C[241,242] but the association of hepatitis C with PCT is lower in northern Europe.[241,243] The high concentration of porphyrins in the liver results in brilliant fluorescence of liver biopsy samples illuminated with a Wood's light (Fig. 12-15). Microscopic examination reveals needle-shaped, fluorescent porphyrin crystals in hepatocytes.[244] Other histologic findings are not specific,[245] but increased hepatocellular iron stores are a nearly constant finding.[246-248]

Pathogenesis. Over 100 URO-D mutations have been identified in patients with PCT.[78] The functional consequences of many of these mutations have been studied,[249] but heterozygosity for mutant URO-D alleles alone cannot explain the phenotype, as half-normal URO-D activity is not rate-limiting. Immunoreactive URO-D in the liver of patients with clinically evident F-PCT is half-normal, yet enzyme activity is 25% of normal or less.[250] No URO-D mutations are found in patients with S-PCT and immunoreactive URO-D in all tissues is normal. When S-PCT becomes clinically evident, immunoreactive URO-D in the liver remains normal, yet enzyme activity is reduced to approximately 25% of normal, the same level of activity found in F-PCT.[251,252] These findings indicate that the specific activity of hepatic URO-D is affected. Furthermore, catalytic activity of URO-D returns to normal after phlebotomy-induced iron depletion,[250] suggesting that an iron-dependent process is responsible for the reduction in the specific activity of hepatic URO-D. Similar findings, a reduction in URO-D activity without a change in URO-D protein, have been noted in several animal models of PCT.[253-257] Collectively, these data suggest a common mechanism in the pathogenesis of PCT, namely generation of an inhibitor of URO-D by an iron-dependent mechanism.

The inhibitor of URO-D in humans with PCT and in animal models of PCT has been identified as uroporphomethene.[258] Uroporphomethene differs from uroporphyrinogen due to oxidation of a single bridge carbon between adjacent pyrrole rings. Uroporphomethene is sufficiently flexible to adapt to the spatial requirements of the active site of URO-D, but the variance from the structure of uroporphyrinogen prevents the inhibitor from serving as a substrate.

Generation of the uroporphomethene inhibitor likely requires liver-specific isozymes of cytochrome P450,[259] but the mechanism of the iron effect remains unidentified. Iron clearly plays a central role because iron depletion through phlebotomy therapy reverses the clinical and biochemical phenotype, even when liver iron content is not clearly elevated.[260] Replacement of iron removed through phlebotomy therapy produces a prompt relapse.[261] Iron depletion prevents or dramatically attenuates the porphyric phenotype in animal models of PCT, and iron supplementation accelerates development of the phenotype.[226,262] Hepcidin, a peptide that regulates systemic iron homeostasis, has been studied in patients with conflicting results. In one study, hepatic expression of hepcidin mRNA was significantly reduced,[263] but in another study, serum hepcidin levels were increased.[264] In spite of these data, very few patients with hemochromatosis or other disorders associated with iron overload develop PCT. Hepatic iron loading, therefore, is not sufficient to produce the PCT phenotype. Other factors, both genetic and environmental, appear to be required to create susceptibility to PCT.[199]

The cutaneous findings in PCT, as in other porphyrias associated with photosensitivity, result from interaction of light with a wavelength of approximately 400 nm (Soret band) with porphyrins that accumulate in the skin.[265] The photoexcited porphyrin returns to a stable state by emitting energy as a photon that disrupts membranes and intracellular organelles.[266] The photodynamic reaction activates inflammatory mediators, which damage the epidermal basement membrane, causing fragility of the skin and blistering.[267] Another prominent site of photodamage is at the vascular level of the skin, where thickening of superficial dermal vessel walls is a constant finding.[268,269]

Laboratory Diagnosis. Laboratory testing is essential for confirmation of the clinical diagnosis of PCT and HEP. The appearance of the skin and skin biopsy findings resemble those of other photosensitizing porphyrias and pseudoporphyria. A useful initial approach to establishing that a porphyric disorder is present is to measure the total porphyrin content of plasma.[270] A normal value excludes the diagnosis of PCT and HEP. If the plasma porphyrin level is high, additional testing is required to distinguish PCT and HEP from HCP and VP. Chromatographic separation and quantification of urinary and stool porphyrins serves this purpose. In PCT and HEP, greatly increased amounts of uroporphyrin and heptacarboxyl porphyrin are excreted in the urine (Fig. 12-16). Urinary excretion of coproporphyrin may be slightly increased.[247,271] Values for daily urine porphyrin excretion average 3000 μg (normal is less than 50 μg) and may be considerably higher. Cutaneous symptoms are usually mild or absent when uroporphyrin excretion is less than 1000 μg/day. A distinctive tetracarboxylic porphyrin, isocoproporphyrin, is excreted in feces, but total fecal porphyrin excretion is normal or minimally increased.[272] HEP can be distinguished from PCT by the presence of anemia and an increase in erythrocyte zinc protoporphyrin.[273]

Erythrocyte URO-D assays can be useful but are not widely available. Furthermore, distinguishing between F-PCT and S-PCT is not critical for patient management. Very low activity of URO-D in erythrocyte lysates can distinguish HEP from F-PCT and would affect therapeutic choices, but directly determining URO-D mutation status is more precise and facilitates genetic counseling.

In patients with PCT, additional laboratory testing is indicated to determine body iron burden (serum iron, total iron binding capacity, and serum ferritin), liver functional status, hemochromatosis genotype, and the presence or absence of antibodies to hepatitis C and human immunodeficiency virus.

Treatment. Two effective forms of therapy have been widely used in patients with PCT, phlebotomy and low-dose chloroquine. Phlebotomy treatment is preferred in patients with marked increases in hepatic iron stores, determined by liver biopsy and serum ferritin values. Removal of 500 mL of blood every 2 weeks for 3 to 4 months will usually suffice,[247,274] but additional treatment is required for patients with hemochromatosis. The objective is to produce iron depletion, not iron deficiency. A useful target is a serum ferritin value of approximately 50 μg/L. Skin lesions clear when urine porphyrin excretion falls below 1000 μg/day, but it may take a year or more for the urine to become completely normal. Relapses are infrequent, especially if risk factors (alcohol and oral estrogens) are avoided. Transdermal estrogen

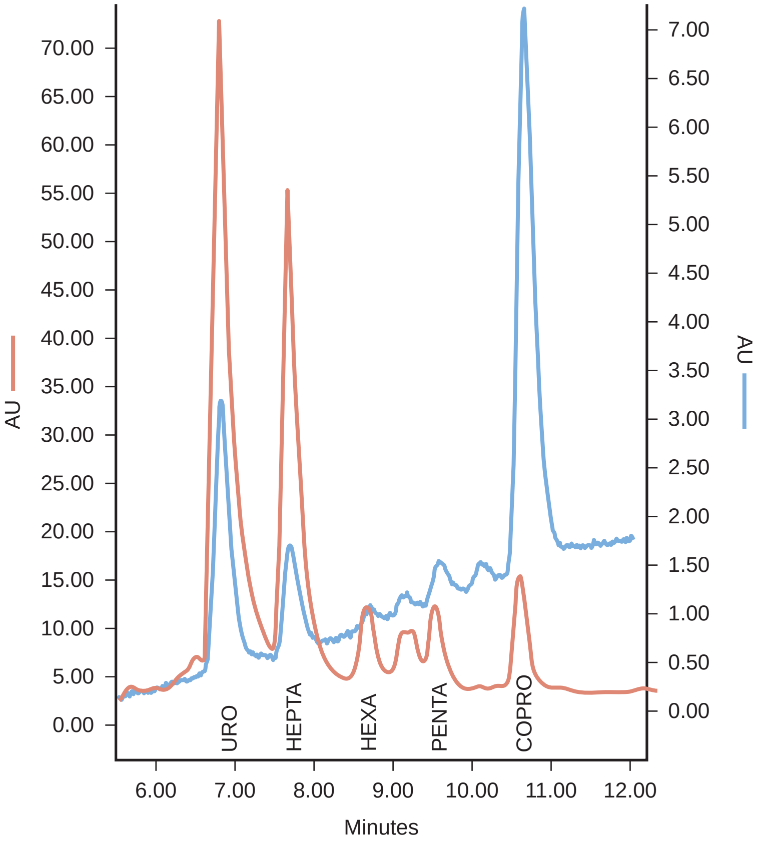

Figure 12-16 Urine porphyrin profile in porphyria cutanea tarda (PCT). Urine porphyrins were separated by high-performance liquid chromatography and quantified fluorometrically. The tracing from a normal person is shown in blue with the scale on the right (0 to 7 absorbance units). The profile of urine porphyrins from a patient with PCT is shown in red with the scale on the left (0 to 70 absorbance units). Uroporphyrin (URO) and 7-carboxyl porphyrin (HEPTA) predominate in the PCT sample, whereas coproporphyrin (COPRO) is the main porphyrin present in normal urine. The intermediate porphyrins with 6- and 5-carboxyl groups (HEXA and PENTA) are also increased in the PCT sample.

administration following phlebotomy-induced remission of PCT in women, however, appears to be safe.[275]

Low-dose chloroquine therapy is an effective alternative treatment and at some centers is preferred for patients with modest iron overload.[276,277] The time required to produce clinical remission is longer than with phlebotomy treatment, but ultimately the results are equivalent. Chloroquine in a dose of 125 mg by mouth twice weekly (or hydroxychloroquine in a dose of 100 mg by mouth twice weekly) will gradually reduce plasma and urinary porphyrins.[278-280] Chloroquine concentrates in the liver, where a water-soluble complex with uroporphyrin is formed, promoting urinary excretion.[281] Higher doses of chloroquine should be avoided because marked hepatotoxicity may occur, an effect that is unique to patients with PCT.[282,283] There is some risk of retinopathy with low-dose regimens,[284] and transient, modest elevations of transaminase values may occur.[247] Because of these potential reactions to low-dose chloroquine regimens, many centers prefer phlebotomy therapy unless comorbid conditions render phlebotomy unsuitable.

In contrast to PCT, phlebotomy therapy is not effective for HEP,[220] and responses to chloroquine are infrequent and suboptimal.[285] Treatment for HEP, as with CEP, is focused on symptomatic relief by avoiding sunlight and the use of protective clothing and topically applied opaque sun screens.

Coproporphyrinogen Oxidase

Copro'gen III, the product of the URO-D reaction, is transported from the cytosol across the outer mitochondrial membrane to the intermembrane space, where CPO catalyzes the sequential oxidative decarboxylation of the propionate groups of pyrrole rings A and B of copro'gen III to form proto'gen IX (Fig. 12-17). CPO in humans, all eukaryotes, and some prokaryotes is an oxygen-dependent enzyme.[286] CPO utilizes two molecules of O_2 and releases two molecules of CO_2 and H_2O.[287,288] It has been suggested that oxygen reacts directly with the targeted pyrrole ring, yielding a hydroperoxide which acts as the electron acceptor.[289] The nuclear-encoded CPO protein possesses an unusually long leader sequence that is required for mitochondrial localization.[10]

The crystal structures of both human and yeast oxygen-dependent CPO have been determined.[290,291] The enzyme functions as a homodimer.[286] The structure of CPO allows the enzyme to maintain the substrate as the reduced porphyrinogen yet permits access of oxygen to the active site for the oxidative decarboxylation reaction and the release of H_2O_2.[290,291] The human CPO gene has been cloned and is located on chromosome 3q12.[292] The CPO promoter region encodes an Sp-1-like element, a GATA site and a novel regulatory element that interacts in a synergistic manner in erythroid cells.[293] The GATA site is not required for transcription in nonerythroid tissues, but the novel regulatory element is necessary. There is increased expression of CPO in erythroid cells, a finding consistent with erythroid upregulation mediated by the GATA site.[294]

Hereditary Coproporphyria

Mutations of CPO are the cause of HCP. The disorder is transmitted as an autosomal dominant trait with low penetrance. Affected individuals and nonpenetrant mutation carriers have half-normal activity of CPO. Acute neurovisceral attacks are identical to those that occur in patients with AIP, but photoinduced skin lesions are occasionally present. Presentation before puberty is extremely rare, but several early-onset cases due to homozygosity or compound heterozygosity for CPO mutations have been reported.[295,296] Homozygosity for a specific CPO mutation is responsible for a rare form of homozygous HCP, designated harderoporphyria, with onset in infancy and with a prominent erythroid phenotype.[297] Harderoporphyrin is a tricarboxylic porphyrin in which the propionate on the A ring is oxidized to a vinyl group, but the propionate on the B ring is not. Harderoporphyrin was named for an unusual porphyrin found in the rat Harderian gland. It was later learned that the porphyrin found in the rat was a glycoconjugate of protoporphyrin and not a tricarboxylic porphyrin, rendering the term *harderoporphyrin* a misnomer.[298]

Frequency. HCP is the least common of the acute neurovisceral porphyrias.[299] Homozygous HCP is very uncommon but important to the pediatrician because clinical

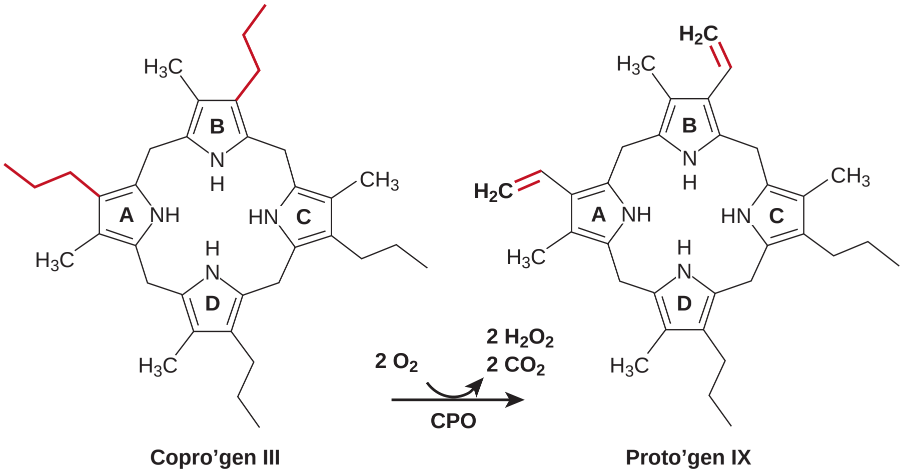

Figure 12-17 Reaction catalyzed by coproporphyrinogen oxidase (CPO). The propionate groups on rings A and B of the tetrapyrrole are sequentially oxidatively decarboxylated, forming vinyl groups. The reaction consumes two molecules of molecular oxygen and produces protoporphyrinogen IX (proto'gen IX) plus two molecules of carbon dioxide and hydrogen peroxide. *Copro'gen,* coproporphyrinogen.

manifestations occur in children. Harderoporphyria is even more rare, with only seven cases reported.

Clinical Manifestations. Acute neurovisceral attacks in patients with HCP are clinically indistinguishable from the acute attacks in patients with AIP. In one series of 53 German patients, abdominal pain was the most common symptom (89%).[300] Neurologic, psychiatric, and cardiovascular symptoms occurred in 25% to 33% of cases. Cutaneous symptoms occurred in only 14%. Similar findings were reported in an earlier series from the United Kingdom, but the incidence of cutaneous findings was slightly higher.[301] The cutaneous findings are the sole feature of HCP that distinguishes an attack from AIP. Most acute attacks of HCP are precipitated by drugs (see Table 12-3),[302] but attacks may also occur in association with menstrual cycles. The cutaneous photosensitivity is manifested mainly as bullous lesions and is generally present only with acute attacks. The bullae resemble those seen in PCT, but the chronic scarring reactions are uncommon because the photosensitivity is intermittent. Rarely, intermittent photosensitivity may be the only clinical sign of HCP.[301] In children who are homozygotes or compound heterozygotes for CPO mutations, the disorder is an early onset phenocopy of clinically affected adults who are simple heterozygotes. Growth retardation, hypertrichosis, and skin pigmentation are additional findings in early onset cases.[295,296]

The clinical manifestations of harderoporphyria are quite different. Hemolytic anemia, intense jaundice, and hepatosplenomegaly are present at or shortly after birth.[297,303] Bullous skin lesions develop if photo therapy for neonatal jaundice is employed. The urine appears red. Nucleated erythrocytes are present on the peripheral blood smear. Exchange transfusions have been helpful. With time, hepatomegaly resolves but splenomegaly remains. The hemolytic anemia becomes partially compensated, and additional transfusions are not necessary. Cutaneous photosensitivity persists and by the teenage years the skin resembles that seen in PCT. Acute neurovisceral attacks occurred in only one of the reported cases, the child homozygous for a H327R mutation.[304]

Four of the seven reported cases of harderoporphyria occurred in three families.[304] In four cases homozygosity for a mutation present in exon 6 (K404E) was detected.[305] In a fifth case the K404E mutation was present on one allele, but a different mutation was found on the other allele (IVS6-+3A>G).[304] In the sixth case a Japanese newborn with jaundice, hemolytic anemia, hepatomegaly, and photosensitivity proved not to be homozygous for a CPO mutation. This child was heterozygous for the K404E mutation, inherited from the father, but enzyme activity was not measured in the child or the parents. A promoter mutation in one maternal allele was suspected as the cause of the harderoporphyria phenotype in the child.[306] A seventh case proved to be homozygous for a H327R mutation.[304]

Pathogenesis. The accumulation and excretion of coproporphyrin is best explained by loss-of-function mutations of CPO but acute neurovisceral attacks, as in AIP, require induction of hepatic ALA-S. Over 50 CPO mutations have been described in patients with HCP and homozygous HCP[307] including large deletions.[78,299,308] The mutation responsible for harderoporphyria, K404E, is of special interest as it mainly effects the second decarboxylation reaction in the conversion of copro'gen III to proto'gen IX. One other mutation, R401W, that was found in a patient with HCP was expressed in vitro and was also found to have a defect in the second decarboxylation.[307] These findings suggest that a region around residues 401 and 404 is important for retaining the tricarboxylic intermediate (harderoporphyrin) in the active site and permitting the second oxidative decarboxylation. The distinctive erythroid phenotype of harderoporphyria is difficult to explain but must be related to a peculiar toxic effect of harderoporphyrin. The accompanying photosensitivity is likely due to the photodynamic properties of coproporphyrin. The roles of ALA and PBG in the pathogenesis of the acute neurovisceral attacks are as described for AIP.

Laboratory Diagnosis. Increased levels of fecal coproporphyrin III are the most prominent findings and are always found in clinically affected cases.[300] The ratio of coproporphyrin III to coproporphyrin I in feces is markedly increased, even in asymptomatic heterozygotes.[300] Urinary excretion of coproporphyrin is markedly increased during acute attacks but generally returns to normal during remission. Similarly, urinary excretion of ALA and PBG is increased during attacks but then returns to normal. When PBG excretion is increased, determining the coproporphyrin isomer ratio and plasma fluorescence scanning serve to establish a diagnosis of HCP.[299] The laboratory findings in homozygous HC are the same, but the abnormalities are more dramatic.

The laboratory findings in harderoporphyria are characterized by the presence of harderoporphyrin in feces along with increased amounts of coproporphyrin III. Urinary excretion of coproporphyrin is also increased, and trace amounts of harderoporphyrin may be found. There is no increase in the urinary excretion of ALA or PBG. Modest increases in erythrocyte protoporphyrin are present, but harderoporphyrin is not present in red cells.[303,305] Iron overload as a consequence of chronic hemolysis and ineffective erythropoiesis has also been reported.[305]

Assays for CPO activity have been utilized but are difficult to perform and are not widely available. Red cells are not a ready source of the enzyme because CPO is localized in the mitochondria. Lymphocytes or cultured cells are required.[70] DNA sequencing is the most direct approach, but the biochemical phenotype is so distinctive that a secure diagnosis can be made by simply analyzing fecal and urine porphyrins. Misdiagnosis of HCP is a common problem because urinary coproporphyrin excretion may be minimally increased in many nonporphyric conditions.

Treatment. Acute neurovisceral attacks are treated as in AIP. Hemin therapy is useful, and regular infusions as maintenance therapy have been successful.[309,310] Although the skin lesions resemble those of PCT, phlebotomy, and chloroquine are not effective. The chronic photosensitivity associated with homozygous HCP and harderoporphyria are best managed with avoidance of sunlight, protective clothing, and opaque sunscreens. The extreme jaundice and hemolytic anemia in newborns with harderoporphyria responds to exchange transfusions. Phototherapy of newborns should be avoided. The chronic compensated hemolytic anemia requires supplementation with folic acid and may require orally administered iron chelators.

ENZYMATIC OXIDATION OF PROTOPORPHYRINOGEN IX TO PROTOPORPHYRIN IX AND INSERTION OF IRON

Protoporphyrinogen Oxidase

Proto'gen IX is oxidized to proto IX by PPO (Fig. 12-18). PPO is functionally conserved in eukaryotes despite a low sequence identity. PPO is an intrinsic protein of the inner mitochondrial membrane and requires molecular oxygen and the cofactor flavin adenine dinucleotide (FAD). Three molecules of oxygen serve as the terminal acceptors in the six-electron oxidation reaction, generating hydrogen peroxide rather than water.[311-313] The reaction proceeds via three two-electron oxidations rather than one six-electron oxidation.[314]

The crystal structure of PPO from multiple species, including human, has been determined.[315-317] In all cases, the enzyme functions as a homodimer. Each monomer contains one noncovalently bound FAD. PPO is synthesized in the cytosol and locates to the inner mitochondrial membrane. It has been proposed that PPO resides on the outer surface,[318] but recent evidence indicates a localization on the mitochondrial matrix side of the inner membrane.[319] The human PPO protein does not contain a cleavable leader sequence but contains a mitochondrial targeting sequence within the first 175 residues. The 28 N-terminal residues have some features of a presequence, which function as an independent mitochondrial targeting sequence.[320,321] Deletion of these residues, however, does not prevent translocation to mitochondria, indicating more distal regions are required for efficient import and insertion into the inner mitochondrial membrane.[321] There is a single 1.8 Kb transcript of PPO in all tissues.[318] The human PPO gene is located on chromosome 1q22-q23.[322,323] The 5' flanking region of human PPO contains a GATA1 binding site, suggesting the potential for erythroid specific regulation. Induction of erythroid differentiation in mouse erythroleukemia cells with dimethylsulfoxide leads to increased expression of PPO.[323]

Variegate Porphyria

VP is transmitted as an autosomal dominant trait resulting from subnormal activity of PPO.[324] The clinical and biochemical features of the disease were first described in 1937,[325] but VP was not recognized as a distinct porphyric disorder until the description by Dean and Barnes in 1955.[326] The term *variegate* was applied when it was recognized that patients had either cutaneous photosensitivity, a predisposition to acute neurovisceral attacks, or both. Presentation before puberty is extremely rare, but early onset with marked photosensitivity has been reported in children homozygous for PPO mutations or with compound heterozygous genotypes.[85] The speculation that VP affected members of the British royal family, including King George III, has been recently discounted.[327]

Frequency. The prevalence of VP in Europe is established at 0.5 per 100,000.[328] The prevalence is higher in Finland, at 1.3 per 100,000,[329] but the disease is extraordinarily common in South Africa, where prevalence is estimated at 3 per 1000 in the white population.[89] The high prevalence in South Africa is due to a founder mutation introduced from the Netherlands in 1688.[330] The connection with the Netherlands has been confirmed by haplotype association studies in South African and Dutch families with VP.[331] Clinical penetrance in earlier reports was estimated at approximately 90%,[332] but the advent of molecular genotyping and sensitive biochemical markers has reduced the estimate to approximately 5% to 10 %.[89,299]

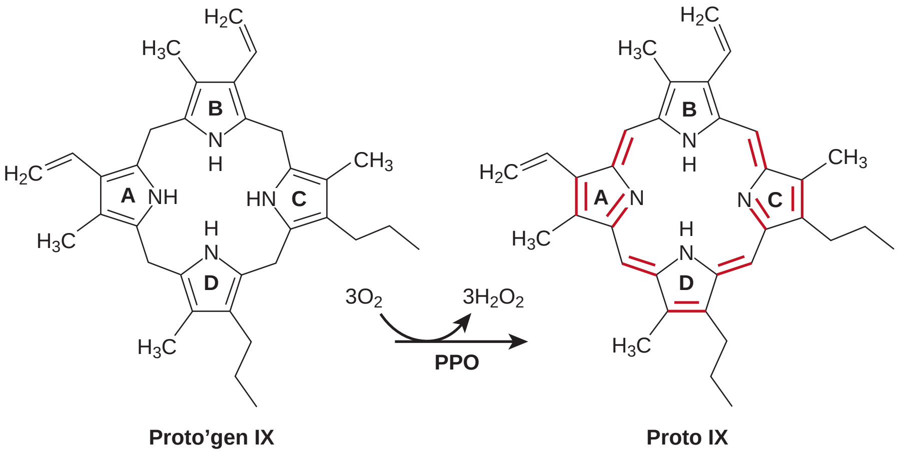

Figure 12-18 Reaction catalyzed by protoporphyrinogen oxidase (PPO). Protoporphyrinogen IX (proto'gen IX) is oxidized to protoporphyrin IX (proto IX) with the loss of six protons. Three molecules of molecular oxygen are consumed, and three molecules of hydrogen peroxide are formed in the reaction.

Clinical Manifestations. The acute attacks in patients with VP are identical to those seen in AIP but occur with a lower frequency and a later age.[89] Skin manifestations in VP are similar to those in PCT[333] and are of long duration. In a heterozygous Western European population of 103 clinically affected patients with VP, 59% had skin lesions only, 20% had acute neurovisceral attacks only, and 21% had both.[334] This distribution is similar to that observed in a 1980 report from South Africa.[332] In contrast recent reports from South Africa and Finland indicate a marked reduction in acute attacks and a less dramatic decrease in photosensitivity—changes thought to be due to systematic detection of mutant PPO alleles in families and the avoidance of potentially harmful drugs.[89,335]

Homozygous VP in two young siblings was first described by Korda and colleagues in 1984.[336] The clinical phenotype differed dramatically from adult onset VP. Marked photosensitivity from birth, mental retardation, and seizures were described, but no acute neurovisceral attacks occurred. Since then, over a dozen additional cases have been described.[337-342] Severe cutaneous manifestations beginning in infancy have been a constant finding. Short stature is common, but mental retardation and seizures are not. A peripheral sensory neuropathy and deformities of the hands were noted in some cases, but in no case was a neurovisceral attack described.

Double heterozygosity for mutant alleles of PPO and CPO has been reported.[343] Surprisingly, the phenotype was mild and restricted to dermal photosensitivity.

Pathogenesis. A wide variety of PPO mutations in families with VP has been reported in different ethnic groups.[334,335,344] A single mutation, R59N, is found in almost all cases in South Africa.[345,346] There appears to be no correlation between specific mutations and the severity of the clinical syndrome.[299] In all cases, the activity of PPO is approximately half-normal.[347,348] The cutaneous manifestations of VP are due to the photodynamic properties of protoporphyrin and coproporphyrin which are produced in excess in the liver. The acute neurovisceral attacks are due to the episodic overproduction of ALA and PBG. The extreme photosensitivity seen in early onset VP is mediated by very elevated plasma porphyrins.[349] Most of the early onset cases have been heteroallelic for PPO mutations (i.e., compound heterozygotes) with markedly reduced PPO activity.[341]

Laboratory Diagnosis. When acute attacks of VP occur, fecal protoporphyrin and coproporphyrin and urinary coproporphyrin are markedly elevated.[335] VP can be distinguished from HCP and AIP by detection in plasma of a characteristic fluorescence emission spectrum with an emission maximum at 626 nm.[350] This emission spectrum results from a dicarboxyl porphyrin bound to plasma proteins.[351] Detection of the 626 nm peak in plasma is a useful method of detecting asymptomatic gene carriers and is more sensitive than fecal porphyrin analysis.[331,352] Urinary ALA and PBG are increased during acute attacks but may be normal during remissions.

Homozygous VP is characterized by markedly increased erythrocyte zinc protoporphyrin levels and elevated stool protoporphyrin and coproporphyrin levels.[85] PPO activity can be measured in cells that contain mitochondria,[353] but enzyme assays are not widely available. Direct fluorometric measurement of plasma porphyrins is probably the most rapid method of establishing the diagnosis of VP. Sequencing of the PPO gene is being applied more widely and is available through the Department of Human Genetics at the Mount Sinai School of Medicine in New York, N.Y.

Treatment. Treatment of acute attacks is as described for AIP and HCP.[354] Protection from sunlight is the only practical way to manage the photosensitivity. Phlebotomy therapy or chloroquine is not effective. A single patient with symptomatic VP has been treated with a liver transplant.[355] The indication for transplantation was advanced alcohol-induced cirrhosis. Following the transplant, fecal porphyrin values returned to normal and no further cutaneous or neurovisceral symptoms occurred. Improved treatment, detection of latent family members, and avoidance of potentially harmful drugs have improved the outcome and reduced disease-related morbidity.[89,331]

Ferrochelatase

The final step in the heme biosynthetic pathway, the insertion of iron into proto IX, occurs on the matrix side of the inner mitochondrial membrane, a reaction catalyzed by FECH (Fig. 12-19). Human FECH has been crystallized, and the enzyme functions as a homodimer.[356] Each monomer of FECH contains a nitric-oxide sensitive 2Fe-2S Fe/S bound to a cysteine-rich site at the C-terminus.[357] It has been suggested that a direct interaction occurs between PPO and FECH.[319] This arrangement would permit direct transfer of proto IX from PPO to the active site of FECH. This mechanism has been questioned, however, as experiments using isolated mitochondria indicate that a complex between enzymes is not required for heme synthesis.[358]

The human FECH gene has been cloned and mapped to chromosome 18q21.3.[359] The same transcriptional start site is used in erythroid and nonerythroid tissues and contains binding sites for both housekeeping and erythroid-specific promoter elements.[360] FECH is synthesized in the cytosol and targeted to mitochondria by sequences in the leader peptide,[361] followed by cleavage to produce the active, mature protein. The first 62 amino acids in the leader sequence are sufficient for mitochondrial targeting, but an additional 11 residues are required for efficient proteolytic processing.[362] Expression of FECH is regulated by intracellular iron levels, likely related to the enzyme's requirement for Fe/Ss.[294] Additional regulatory effects occur through interactions with hypoxia-inducible factor.[363]

Erythropoietic Protoporphyria

EPP is an inherited disorder of heme biosynthesis characterized clinically by the onset in childhood or infancy of acute photosensitivity of sun-exposed skin. The disorder was first recognized in 1953 by Kosenow and Treibs[364]

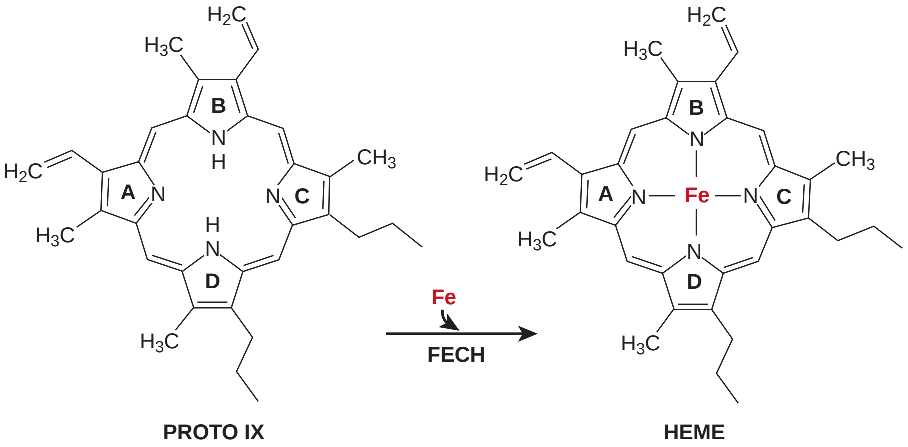

Figure 12-19 Reaction catalyzed by ferrochelatase (FECH). The final step in the synthesis of heme is insertion of ferrous iron into the protoporphyrin IX (proto IX) macrocycle with the release of two protons.

but was clinically characterized and named EPP by Magnus and colleagues in 1961.[365] The inherited nature of the disease was first reported by Haeger-Aronsen in 1963.[366] In most cases EPP is an autosomal recessive disorder due to deficient activity of FECH associated with loss-of-function mutations of one FECH allele coupled with a low expression abnormality (hypomorph) on the other allele.[367] In 2% to 10% of cases no FECH mutations can be identified.[299,368] Most cases of EPP without FECH mutations are due to gain of function mutations of ALA-S2 and are now referred to as X-linked protoporphyria (XLPP) (see later). In one large series from the United Kingdom, 6% of patients with the EPP phenotype had no mutations in FECH or ALA-S2,[369] suggesting other genetic causes for the EPP phenotype are possible. Rare cases with neither FECH nor ALA-S2 have been associated with abnormal expression of mitoferrin-1,[370,371] a protein required for mitochondrial iron assimilation. Excess proto IX generated in erythrocytes causes liver damage in approximately one third of patients with EPP,[372] but severe cholestatic liver disease requiring liver transplant is much less common.[373]

Frequency. The prevalence of clinically manifest EPP has been difficult to estimate but is probably close to that of AIP.[80] In the European immigrant population of South Africa, clinically manifest EPP is estimated to occur in 6.6 individuals per million.[374] The prevalence in the United Kingdom is approximately 7.7 per million.[375] Prevalence estimates for Northern Ireland and the Netherlands have approached 13 per million,[376,377] a finding attributed to a founder effect.[378] A report from Slovenia estimated an even higher prevalence at 17.5 per million.[379] EPP is pan-ethnic but is extremely rare in individuals of African descent.[374]

Clinical Manifestations. The dominant clinical feature of EPP is cutaneous photosensitivity in response to sun exposure with onset in infancy or childhood.[380,381] The clinical picture is very different in comparison to the other photosensitizing porphyrias. Patients develop a characteristic burning pain, erythema, and edema as an acute response to sun exposure.[375] Early in the course of EPP the burning discomfort may occur in the absence of objective cutaneous findings.[382,383] Bullous lesions, pigment changes, and scarring are very uncommon. Instead the skin develops a leathery characteristic that mimics premature aging. The symptoms and objective skin findings change little over time, but increased sun tolerance has been reported during pregnancy.[384,385]

A mild, microcytic anemia is common,[381,386-388] presumably due to impaired heme synthesis. Iron may accumulate in the cytosol and mitochondria of erythroblasts, but this is uncommon.[389] A similar microcytic anemia develops in a mouse model of EPP due to homozygosity for mutant FECH alleles.[390] Serum ferritin values in humans with EPP are reduced, but erythropoiesis does not appear to be iron limited.[387]

Gallstones occur in approximately 10% of patients with EPP and tend to occur early in life.[381,391] The gallstones contain proto IX, which becomes insoluble in bile and alters the solubility of other components of the bile.[392,393] In a mouse model of EPP a strain that sequestered protoporphyrin in the cytosol of hepatocytes and Kupffer cells was protected from cholestatic liver disease.[394] When gallstones occur in children, a diagnosis of EPP should be considered.[395] Minor abnormalities in liver function tests, mainly transaminase elevations, are common,[380] and liver biopsies may demonstrate protoporphyrin deposition and periportal fibrosis.[381,396-398]

Between 1 and 5% of patients with EPP will develop severe cholestatic liver disease progressing to portal hypertension and fatal decompensated cirrhosis.[399-401] Rarely, acute liver failure may be the presenting feature of EPP.[402,403] Over 50 fatal cases of EPP-related liver disease have been reported,[376,399,404,405] including two teenagers and an 11-year-old child.[376]

Pathogenesis. Over 120 mutations in the FECH gene have been detected.[78] The mode of Mendelian transmission had been described as autosomal dominant with incomplete penetrance, but heterozygotes expressing the clinical phenotype have consistently shown FECH activity between 15% to 20% of normal.[406] This was explained by a proposed dominant negative effect in which both mutant–mutant homodimers and mutant–wild type homodimers are catalytically inactive, with only wild type–wild type homodimers responsible for the measured enzyme activity. This theory was discarded with the discovery of a hypomorphic FECH allele, and EPP is now considered an autosomal recessive disorder.[407-409] An intragenic polymorphism (IVS 3-48C) in intron 3 is responsible for low expression of the hypomorphic allele. This polymorphism favors the use of a cryptic acceptor splice site 63 bases upstream of the normal splice site. The aberrantly spliced mRNA contains a premature stop codon and is degraded by a nonsense-mediated decay mechanism.[409] The result is a lower steady state level of wild type FECH mRNA. Most clinically evident cases of EPP are due to coinheritance of the hypomorphic allele in trans to a loss-of-function mutant allele. This genetic combination was found in 98% of French cases with EPP[410] and with a similar frequency in South African patients.[374] The frequency of the IVS 3-48C hypomorphic allele varies widely in different populations and relates to the observed differences in the prevalence of EPP.[410,411]

A rare exception to the compound heterozygous mutant/hypomorph genotype is inheritance of two loss-of-function FECH alleles. This autosomal recessive form of EPP was found in 4% of patients with EPP in the United Kingdom[369] and in occasional cases from other countries.[374,406,412-414] This form of EPP may carry a higher risk of severe liver disease.

Laboratory Diagnosis. The free erythrocyte protoporphyrin concentration is markedly increased in symptomatic EPP.[381,415] Values ranging from 6- to 100-fold greater than normal have been reported. Elevated erythrocyte protoporphyrin levels are also found in patients with iron deficiency and lead poisoning, but in these conditions the elevation is less dramatic, and it is zinc protoporphyrin that is present.[416] Zinc protoporphyrin can easily be distinguished spectrally from the free protoporphyrin found in EPP.[417] Zinc protoporphyrin can also be distinguished from free protoporphyrin by chromatographic techniques.[70] An elevated plasma porphyrin level confirms the presence of a porphyric disorder, but false negative results may be obtained in patients with EPP because protoporphyrin is particularly susceptible to photodegradation.[418] Care must be taken to shield the plasma sample from sunlight or fluorescent lighting.

Fecal protoporphyrin excretion may be increased up to fifteenfold, but values vary widely from patient to patient.[419] Urinary excretion of ALA and PBG are normal. Protoporphyrin, a highly hydrophobic compound, is not excreted in the urine.

Assays for FECH activity are not widely available. FECH mutation detection is the most direct approach to confirm the diagnosis of EPP. Molecular studies are also the only reliable method for identifying asymptomatic cases in families with an affected proband.

Treatment. The therapy of EPP has two objectives. First an attempt should be made to minimize the harmful effects of exposure to sunlight. Protective clothing and opaque sunscreens can be helpful as with other photosensitizing porphyrias. Tolerance to sunlight can be improved in most patients with EPP by inducing carotenemia. This can best be accomplished by administering β-carotene beadlets (Lumitene, Tishcon Corp., Westbery, N.Y.) in doses ranging from 120 to 300 mg/day.[420,421] The only side effect is a dose-related, yellow-orange discoloration of the skin.[422,423] The mechanism of action of β-carotene likely involves quenching of singlet oxygen species or free radicals.[424] A clinical trial of an α-melanocyte–stimulating hormone to darken skin color demonstrated increased tolerance to sun exposure and improved quality of life in patients with EPP.[425,426]

The second objective of therapy is to minimize the hepatotoxic effects of protoporphyrin. Cholestyramine can interrupt the enterohepatic circulation of protoporphyrin excreted in bile and promote fecal excretion. This has been moderately effective in some patients.[392] A variety of other measures have been employed when liver function deteriorates, including plasmapheresis, hemodialysis, exchange transfusions, and suppression of erythropoiesis.[399] In the small proportion of patients with EPP that develop liver failure, liver transplantation is the only effective therapy.[115,373,399,427,428] Liver transplantation, however, does not address the underlying overproduction of protoporphyrin in the native marrow, leading to a high risk of recurrent disease in the transplanted liver.[373,429,430] This complication can be avoided with a bone marrow allograft from an appropriate donor.[428,431,432]

Late-Onset Erythropoietic Protoporphyria. Over a dozen cases of late-onset EPP have been reported.[433-436] Most were associated with myelodysplastic syndromes, but EPP and myeloproliferative disorders have also been reported.[436] All have been due to somatic mutations in hematopoietic clones that result in markedly reduced FECH activity. Two cases were associated with hepatic failure.[436,437]

X-Linked Protoporphyria. Incorporation of gene sequencing in the diagnostic approach to the porphyrias has resulted in several unexpected findings. FECH sequencing and gene dosage analysis of a large number of EPP patients referred to centers in the United Kingdom and South Africa revealed FECH mutations or deletions in most, but no FECH gene abnormalities were found in approximately 7% of cases.[27] Whatley and colleagues studied eight families with mutation-negative EPP.[27] These families were unusual because they displayed a dominant pattern of transmission with an absence of father-son transmission, a finding suggesting X-linkage. Erythrocyte protoporphyrin concentrations were higher than in other EP patients, and the percentage of the zinc chelate was markedly higher (median 44% versus 8%). The cause of the EPP phenotype in these families proved to be increased activity of ALA-S2 due to mutations affecting the carboxy-terminal amino acids.

In six families, deletion of codons 1706 to 1709 (delAGTG) altered the last 19 carboxy-terminal amino acids and elongated the mutant enzyme by four residues. In two families, deletion of codons 1699 to 1700 (delAT) resulted in a frame shift that deleted the 20 terminal residues. Expression of these mutant ALA-S2 enzymes in a bacterial system revealed an increase in enzyme activity compared to wild-type ALA-S2. The end effect of these gain-of-function ALA-S2 mutations is an increase in the production of protoporphyrin that exceeds the capacity of the FECH reaction to generate heme. The generation of large amounts of zinc protoporphyrin suggests that the metal chelating properties of FECH have not been exceeded and that mitochondrial iron delivery limits heme synthesis.

The findings of Whatley and colleagues have been confirmed by Balwani and colleagues in a study of 155 North American patients with the EPP phenotype.[368] FECH sequencing and dosage analysis revealed FECH gene abnormalities in 140 cases. The remaining 15 cases (10% of the EPP patients studied) had ALA-S2 gain-of-function mutations. Thirteen had the previously described ΔAGTC mutation. Two new mutations were found. A single base deletion at codon 1734 (delG) altered the nine carboxy-terminal amino acids and elongated the enzyme by five residues. A nonsense mutation at codon 1642 (C>T) resulted in a Q548X change, which deleted the terminal 40 amino acids. Ducamp and colleagues also detected the Q548X genotype in an Australian patient and the ΔAGTC mutation in two European cases.[438] A novel 26 bp exon 11 deletion affecting codons 1651 to 1677 was also found in a Dutch patient whose parents were from Afghanistan. All of the cases described by Ducamp and colleagues were women.

To-Figueras and colleagues studied four unrelated Spanish patients with CEP with the same URO3-S genotype (C73R/P248Q). The clinical phenotype was similar in three, but the fourth, a young girl, had a more severe phenotype.[171] She proved to have a novel gain-of-function mutation (Y586F) affecting the carboxy-terminus in one allele of ALA-S2.[171] This case suggests that ALA-S2 can act as a modifier gene influencing the phenotype of other erythropoietic porphyrias.

Pathogenesis. The mechanism by which alterations in the carboxy-terminus of ALA-S2 results in increased enzymatic activity has not been clarified, but several hypotheses have been suggested. Structural studies demonstrated that the carboxy-terminus of mammalian ALA-S2 forms a loop over the active site of the enzyme.[8] The open position favors dissociation and release of ALA and thus affects the overall catalytic activity.[8] It has also been suggested that the open position increases substrate access to the active site, resulting in increased enzymatic activity.[439] Finally, the carboxy-terminus of ALA-S2 affects the stability of the enzyme, and certain carboxy-terminal mutations can increase the stability and enzymatic activity.[440] The regulatory effects of the carboxy-terminus are complex because this region of ALA-S2 is responsible for binding to the β subunit of succinyl-CoA synthase, an enzyme that generates one of the substrates for ALA-S2.[441] Mutations in the carboxy-terminus that ablate the succinyl-CoA synthase binding site cause loss-of-function changes in ALA-S2 and X-linked sideroblastic anemia,[441] yet the Q548X mutant enzyme, which does not bind succinyl-CoA synthase, has increased activity and causes XLPP.[439] These findings suggest that conformational changes associated with the carboxyl-terminus of mammalian ALA-S1 are the main mechanism determining specific activity. A number of diverse site-directed mutations of nonconserved loop residues yield hyperactive ALA-S2 variants.[442]

Clinical Manifestations. The clinical findings in patients with XLPP, with one exception, resemble those in FECH-deficient EPP. Erythrocyte and plasma protoporphyrin levels are higher and protoporphyric liver disease is more common.[27,368] Disease expression in females is similar to males, although one asymptomatic obligate female carrier has been described.[27] The single exception is the level of zinc protoporphyrin, which is strikingly higher (30% to 40% of total porphyrin) in XLPP.

Treatment. Strong consideration should be given to bone marrow transplantation when signs of progressive liver disease are recognized.

Late-Onset X-linked Erythropoietic Protoporphyria. Acquired clonal hematopoietic disorders such as myelodysplastic syndromes and myeloproliferative disease have been associated with late-onset cases of CEP and EPP. A case of late-onset X-linked EPP has recently been reported.[443] An 89-year-old French man with a myelodysplastic disorder developed a somatic mutation of ALA-S2 (Q548X) in a hematopoietic stem cell clone. In addition to photosensitivity, the patient had gallstones and cholestasis.

CHAPTER OUTLINE

PRIMARY AUTOIMMUNE HEMOLYTIC ANEMIA
Incidence
Natural History
Clinical Manifestations
Routine Laboratory Evaluation
Serologic Laboratory Evaluation
Differential Diagnosis
Characteristics of Erythrocyte Autoantibodies
Therapy
Pathogenesis of Autoantibody Formation
SECONDARY AUTOIMMUNE HEMOLYTIC ANEMIA
Evans Syndrome
Acute Lymphoproliferative Syndrome
Immunodeficiency
Other Systemic Disorders
Infections
Drugs

Autoimmune hemolytic anemia (AIHA) is an immunologic disorder in which antibodies are produced that target red blood cells (RBCs).[1,2] AIHAs can be classified into four major types of disease: warm-reacting AIHA, cold agglutinin disease (CAD), paroxysmal cold hemoglobinuria (PCH), and mixed-type AIHA (Box 13-1). Patients with no underlying associated diseases are classified as having primary or idiopathic AIHA. AIHA in patients with associated autoimmune diseases, immunodeficiencies, or infectious diseases is classified as secondary. Drug-induced and alloantibody-mediated immune hemolytic anemias are other important causes of antibody-mediated RBC destruction.

Antibodies produced are of two major classes: immunoglobulin G (IgG) and immunoglobulin M (IgM). IgG-coated RBCs are recognized by macrophages with specific receptors on their surface that are efficient in binding and stimulating the ingestion of the IgG-coated cells.[3-5] In addition to the clearance of IgG-coated RBCs by macrophages, patients with AIHA can also have IgM antibodies or, rarely, immunoglobulin A (IgA) antibodies directed at the RBC. The macrophage Fcγ receptors primarily responsible for the clearance of IgG-coated cells are FcγRI, FcγRIIIA, and FcγRIIA.[6] IgM antibodies bound to the RBC surface can initiate activation of classic complement pathway, resulting in the deposition of complement components—usually C3b. C3b-coated RBCs are recognized by macrophage C3b receptors, which then internalize complement-coated RBCs. IgG antibodies, when present on the RBC surface at a sufficient antigen density, can also induce complement activation.[7,8]

Finally, both IgG and IgM antibodies can induce the clearance of the antibody/complement-coated RBCs by tissue macrophages. The tissue macrophages responsible for the clearance of IgG-coated RBCs are present in the spleen. Hepatic macrophages can also bind C3b-coated RBCs and initiate their clearance. Rarely, RBCs coated with other antibody subclasses such as IgA can be present and induce the accelerated clearance of these RBCs, which occurs in a rare subset of patients with AIHA.

PRIMARY AIHA

Incidence

Primary AIHA is relatively uncommon, with an annual incidence of about 1 per 75,000 to 80,000 persons.[2,9] Within the pediatric population, AIHA is primarily a disease of young children,[10,11] with a median age of diagnosis of 3.8 years in a recent national observational study.[11] Primary AIHA also affects infants and toddlers, typically after a recent infection,[10-12] whereas adolescents with AIHA are more likely to have an associated underlying systemic illness and to have secondary disease.[13] Gender preference is unclear; some studies show an equal male to female ratio,[11,14] whereas other authors report a slightly higher prevalence in young boys but equal

prevalence between the sexes during adolescence.[15] No evidence exists that AIHA affects persons of any particular racial background.

Warm-reactive antibodies are primarily of the IgG class and account for the majority of AIHA cases in children.[11,13] IgM-mediated CAD is uncommon in children and mostly affects middle-aged adults and elderly persons.[16] In contrast, PCH primarily presents in children, with the median age at diagnosis being 5 years.[17]

Natural History

Young children with IgG warm-reactive AIHA can have an acute illness only but tend to have a chronic clinical course characterized by intermittent remissions and relapses. In contrast, patients with cold-reactive autoantibodies, a condition most commonly associated with PCH, may have severe but acute self-limited illness requiring short-term supportive care with transfusion.

Overall mortality rates of 11% to 18% were reported in older series of pediatric AIHA cases,[10,13,18] but in a recent study of 265 pediatric patients with AIHA, only 4% of children died.[11] The improved mortality rate is likely a result of improvement in supportive care and new immunosuppressive treatment options, such as rituximab.[19,20,21] Pediatric patients who have primary AIHA associated with an infectious etiology have the most favorable outcome, with very low mortality and a high complete remission rate.[11] In this largest cohort of 265 pediatric patients with AIHA, the median evaluable period was 3 years, and it was longer than 1 year for 198 children. More than one third (37%) were diagnosed with Evans syndrome. At the last follow-up, 4% had died, 6% had no response or were in partial remission, and 90% were in complete remission while either receiving or not receiving therapy.[11] Because AIHA is a rare disease, data describing the incidence of acute versus chronic disease are lacking.

Several studies have attempted to define prognostic factors for pediatric AIHA. A positive mixed IgG/C3 direct antiglobulin test (DAT) is more likely associated with chronic disease as an independent prognostic risk factor.[11,13,18] In earlier retrospective studies it was observed that younger children with an abrupt onset of symptoms have a better prognosis.[10,13] In the context of current therapies, sex, age, and the triggering infection were not associated with continuous complete remission.[11]

Clinical Manifestations

Patients with AIHA typically present with symptoms of anemia such as pallor or fatigue, and they sometimes present with jaundice and scleral icterus as a result of rapid erythrocyte destruction and increased bilirubin turnover. Dark urine is reported in up to 80% of cases.[10,11,13] Hemoglobinuria is attributed to intravascular hemolysis of erythrocytes and therefore may occur in cases of cold AIHA as a result of IgM-mediated complement activation, but it is uncommon in persons with IgG-associated warm autoantibodies. The onset of symptoms can be rapid but the child is usually well compensated from a cardiovascular standpoint, and symptoms of congestive heart failure or circulatory collapse are rare. Occasionally fever or abdominal pain is reported by the patient.

Children with AIHA often have a benign medical history, but questions should be asked to determine whether a previous similar episode has occurred or if the child has had a recent viral illness. A history of infections, exposure to drugs or vaccination, or signs of immune disease may suggest secondary AIHA. The review of systems should include questions that address a possible underlying autoimmune disease, primary immunodeficiency, inflammatory disorder, or malignancy. The family history is often not revealing, but familial cases of AIHA have been reported[10] and likely represent a familial predisposition to an autoimmune disorder such as systemic lupus erythematosus (SLE).

The physical examination can be normal in patients with mild anemia, but children with moderate to severe AIHA are usually pale and icteric. Jaundice, which may be particularly prominent when ongoing hemolysis is severe, is caused by the breakdown of bilirubin from the destroyed erythrocytes. However, it should be emphasized that complement-coated RBCs are cleared extravascularly and that RBCs are difficult to lyse after complement activation. With less brisk hemolysis, jaundice may be best appreciated in the eyes or in the palms or soles. A heart examination will show that most children are tachycardic and, depending on the degree of anemia, an early systolic flow murmur may be appreciated as a result of the high output anemic state. A gallop may be heard in severely anemic patients and is a sign of impending cardiac failure. Mild to moderate tender splenomegaly is common in patients with severe hemolytic anemia, and occasionally hepatomegaly may occur as well.

Intravascular hemolysis results in hemoglobinemia and hemoglobinuria when hemoglobin is released into the blood and immediately bound by haptoglobin for clearance in the liver. The rate of hemolysis may exceed haptoglobin production, and extra hemoglobin circulates freely, causing hemoglobinemia. Free hemoglobin is typically filtered in the kidneys and reabsorbed in the form of iron. However, if the hemolysis exceeds the reabsorptive capacity of the renal tubules, hemoglobinuria occurs and urinary hemosiderin is detected. Patients with intravascular hemolysis may experience acute abdominal pain, costovertebral angle tenderness, and fever. Extravascular hemolysis occurs via antibody-coated RBC clearance by splenic and liver macrophages. Patients often present with tender splenomegaly, and although hyperbilirubinemia and bilirubinuria are common, hemoglobinemia and hemoglobinuria are not characteristic.

Routine Laboratory Evaluation

By definition, patients with AIHA present with anemia that ranges from mild to life-threatening. Children with primary AIHA often present with marked anemia, with a hemoglobin concentration of 4 to 7 gm/dL and no apparent cardiovascular compromise. Most patients have a normal platelet count, mild leukocytosis, and neutrophilia, but occasionally patients have leukopenia, neutropenia, or thrombocytopenia.[10,11,13,18] If the thrombocytopenia is significant, a diagnosis of Evans syndrome is possible and antiplatelet antibodies should be assayed.[22] However, microangiopathic hemolytic anemias including thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS) must also be considered with concurrent thrombocytopenia. The reticulocyte count is usually elevated to compensate for the anemia, but more than one third of patients have a transient reticulocytopenia despite having normal or hyperplastic erythroid marrow.[18,23] The mechanism for reticulocytopenia is not well understood, but it has been suggested that a distinct autoantibody directed at erythroid progenitor cells leads to their selective destruction.[24] Bone marrow examination is not typically indicated but shows erythroid hyperplasia in the majority of patients.[18,23]

Evaluation of the peripheral blood smear can reveal important diagnostic hallmarks of AIHA. Spherocytes are usually present in IgG-mediated warm-reactive AIHA (Fig. 13-1), which suggests an immune hemolytic process in the absence of hereditary spherocytosis. Spherocytes result from spleen-induced damage to antibody-coated erythrocytes and are most commonly seen with warm, IgG-mediated AIHA.[25] Spherocytes are uncommon in cold-reactive AIHA, but complement-mediated immune spherocytosis can also result from surface microfragmentation of erythrocytes, and occasional to rare spherocytes are noted on the blood smear.[26] Polychromasia can be appreciated and usually correlates to the degree of reticulocytosis. Other morphologic abnormalities include fragmented and nucleated RBCs. Erythrophagocytosis is a

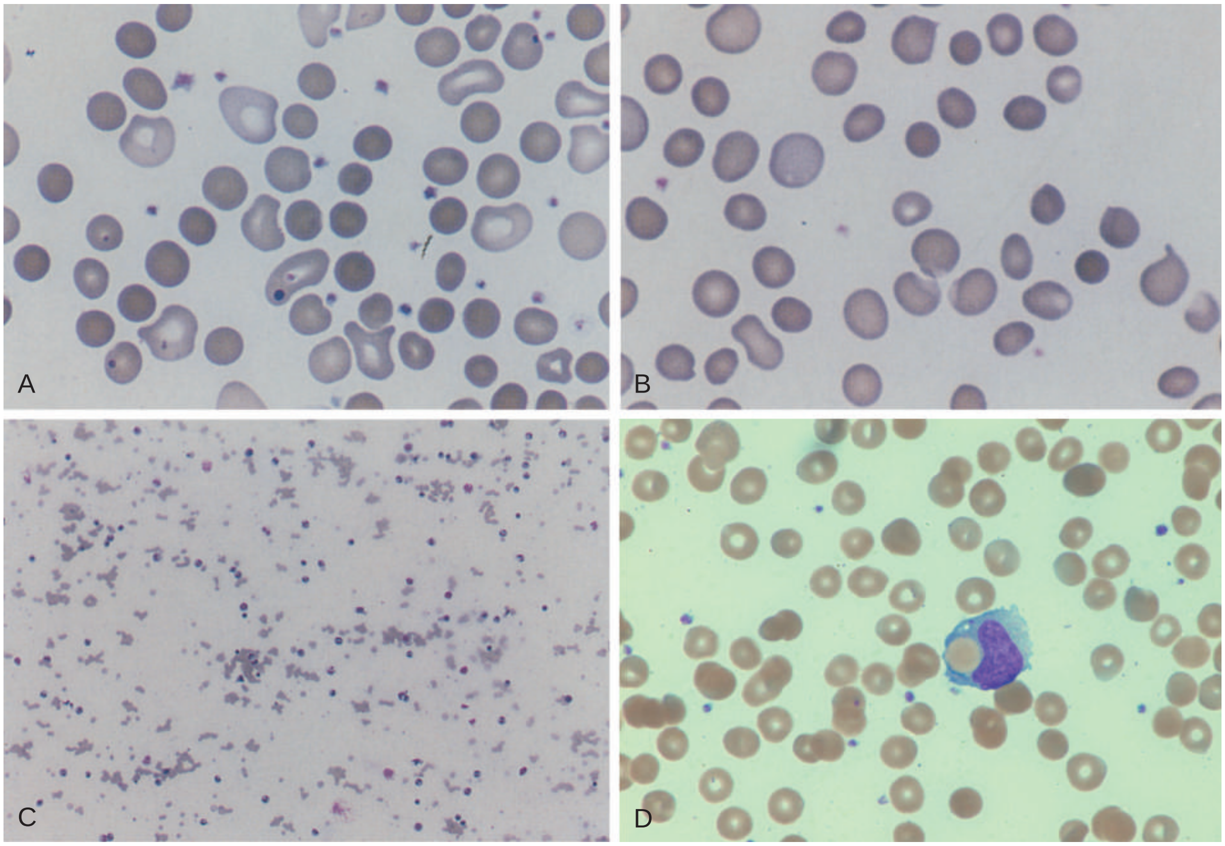

Figure 13-1 Examination of peripheral blood from persons with autoimmune hemolytic anemia (AIHA). **A,** Blood from a patient with immunoglobulin G (warm-reactive) AIHA illustrates many small microspherocytes and larger reticulocytes (×1000), and **B,** blood from a patient with hereditary spherocytosis illustrates the morphologic similarities between these two conditions. **C,** Agglutinated erythrocytes from a patient with immunoglobulin M (cold-reactive) AIHA are clearly visible at low power (×400). **D,** Erythrophagocytosis by a peripheral blood monocyte (×1000). *(From Ware RE: Autoimmune hemolytic anemia. rare finding on the peripheral blood smear but demonstrates monocytes engulfing erythrocytes. Agglutination of RBCs is frequently seen in IgM-mediated cold-reactive AIHA when the binding affinity of the antibody reaches room temperature.

Serum chemistries may be abnormal as a result of erythrocyte hemolysis but are not essential to the diagnosis of AIHA. Elevated levels of lactate dehydrogenase and aspartate aminotransferase reflect erythrocyte destruction and release of cellular enzymes. In contrast, the serum level of hepatic enzymes alanine aminotransferase and gamma glutamyl transferase should not be elevated in persons with AIHA. The total serum bilirubin level is elevated in most patients with AIHA and is primarily unconjugated as a result of accelerated erythrocyte destruction rather than intrinsic hepatic disease. A decreased haptoglobin level is indicative of rapid intravascular hemolysis when the rate of hemolysis exceeds haptoglobin production by the liver. However, haptoglobin levels will be low in newborn infants who do not synthesize it well or high with concurrent infection or inflammation as an acute-phase reactant.[27] Urinalysis may be unremarkable, but when hemoglobinuria is present, urine dipstick analysis shows the presence of blood, although microscopic examination reveals few if any erythrocytes. Urine hemosiderin is detected in patients with hemoglobinuria as a result of intravascular hemolysis and can be used to distinguish hemoglobinuria from hematuria and bilirubinuria.

Serologic Laboratory Evaluation

The DAT (formerly named the Coombs test) is a simple but important test to establish a suspected diagnosis of AIHA. The DAT detects immunoglobulin and/or complement on the surface of RBCs and aids in the classification of hemolysis as immune or non–immune mediated. The test was first reported in the early 1900s but its use became widespread after it was described in 1945 by Coombs and colleagues.[28] Initially this test was used to demonstrate antibody in the serum, but it was later adapted to demonstrate the in vivo coating of RBCs with antibody or complement components.

IgM autoantibodies are pentameric and can bridge and agglutinate adjacent RBCs (Fig. 13-2). In contrast, IgG autoantibodies are smaller and unable to bridge adjacent RBCs because of the surface repulsion between cells, known as the zeta potential. Antihuman globulin (AHG; Coombs reagent) binds to IgG autoantibodies on the RBCs, bridges the zeta potential, and causes agglutination.

The main principle of the DAT is that AHG agglutinates antibody-coated cells, as evidenced by erythrocyte clumping. Ethylenediaminetetraacetic acid (EDTA)–anticoagulated blood samples are preferred because EDTA prevents in vitro fixation of complement.[29] The DAT is optimally performed with use of freshly washed RBCs; washing is necessary to remove proteins and complement that are present in the surrounding plasma and could neutralize the AHG reagent, causing a false-negative result. Typically a polyspecific AHG containing both anti-IgG and anticomplement is used first. A positive DAT result with polyspecific AHG leads to testing with monospecific IgG and complement.[30] Commercial reagents of anti-IgG recognize the gamma heavy chain portion of IgG, and monospecific anticomplement reagents usually contain anti-C3d, which is indicative of bound IgM.[31] The DAT is typically performed at room temperature (25°C) but can be performed at temperatures between 0°C and 37°C to determine thermal reactivity of the antibody. The DAT may be performed with the conventional test tube method, a gel microcolumn technique, or solid-phase methods (Fig. 13-3).

The DAT results describe the pattern of agglutination with the polyspecific AHG reagent and, if positive, the results of subsequent testing with the specific IgG and C3 reagents. The DAT is positive when agglutination is observed either after immediate centrifugation or after centrifugation following a room-temperature incubation.[29] IgG-coated RBCs usually agglutinate immediately, whereas complement-coated RBCs may be more easily demonstrable after incubation.[29] The DAT may also be performed at different temperatures including 4°C, 10°C, 25°C (room temperature) and/or 37°C to distinguish warm and cold-reactive autoantibodies and to characterize their thermal reactivity and amplitude. DAT agglutination results are scored on a scale of 1 to 4.

The presence of IgG on the erythrocyte in a patient with suspected AIHA who has not undergone transfusion is good evidence for an IgG autoantibody. Warm-mediated AIHA is the most common form of AIHA in children and

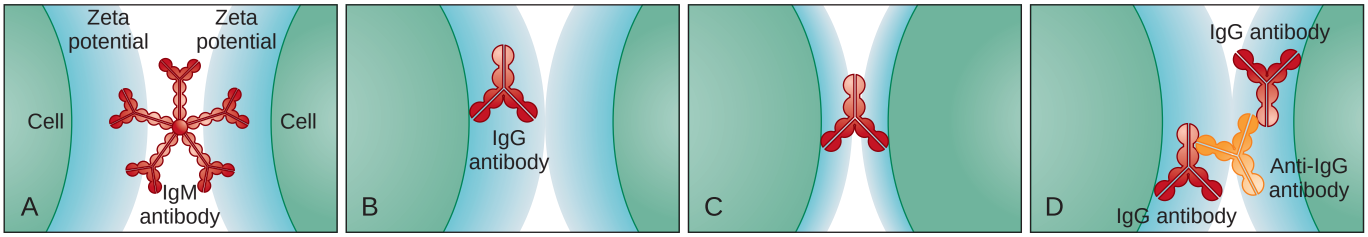

Figure 13-2 Interactions between immunoglobulin molecules and the erythrocyte during agglutination tests and the direct antiglobulin test. **A,** An immunoglobulin M *(IgM)* autoantibody can simultaneously bind two erythrocytes because of its multiple antigen-binding sites. The large size of the IgM molecule allows it to bridge the zeta potential between erythrocytes and cause agglutination. **B,** An immunoglobulin G *(IgG)* autoantibody is too small to bridge the zeta potential. **C,** There is no agglutination of erythrocytes unless the zeta potential is reduced. **D,** Upon addition of the Coombs reagent (a rabbit antiglobulin that recognizes human IgG), the zeta potential is successfully bridged and red cells agglutinate. *(From Ware RE: Autoimmune hemolytic anemia. In Orkin SH et al., editors:* Nathan & Oski's hematology of infancy and childhood, *7th ed. Philadelphia, 2009, Saunders, p. 613–658.)*

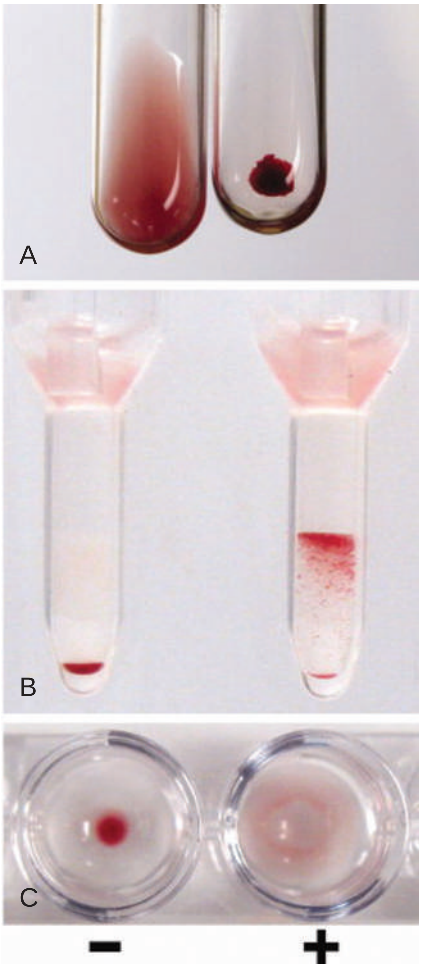

Figure 13-3 Negative and positive direct antiglobulin test (DAT) reactions. The DAT detects immunoglobulin and/or complement on the surface of red blood cells, which agglutinate with the addition of antihuman globulin. The agglutination is detected visually as clumps of red blood cells by the conventional test tube method (**A**), by the failure to filter through a gel matrix in the gel microcolumn method (**B**), or by the adherence of red blood cells onto the surface of a well in solid phase methods (**C**). *(From Zantek ND, Koepsell SA, Tharp DR, Jr, et al.: The direct antiglobulin test: a critical step in the evaluation of hemolysis.* Am J Hematol *87:707–709, 2012.)*

is usually caused by IgG autoantibodies that react at room temperature or 37°C. The DAT is positive for IgG, and simultaneous detection of complement indicates that the antibody can fix complement as well. Cold AIHA is typically caused by IgM autoantibodies that bind to RBCs at temperatures between 0°C and 37°C.[16] A DAT that indicates the presence of complement alone suggests a cold-reactive antibody that fixes complement at lower temperatures but binds poorly to the erythrocyte at 37°C. Further serologic evaluation for the presence of an IgM autoantibody or the IgG Donath-Landsteiner autoantibody would be indicated (described in detail later in this chapter).

The DAT results may be negative despite good clinical evidence of autoimmune hemolysis.[32] DAT-negative AIHA represents 5% to 10% of all AIHAs.[33,34] One explanation is that the quantity of RBC-bound IgG is below the threshold of the DAT with standard reagents,[35-37] which currently detects as few as 150 IgG molecules per erythrocyte. More sensitive assays to detect RBC-bound IgG may be helpful and include enzyme-linked immunosorbent assays,[38] gel card analysis,[39] and flow cytometry.[40] Autoantibodies of the IgA or IgM subtypes may cause hemolysis with a negative DAT because the test is designed to detect IgG and C3d.[41] Reagents that react with IgA or IgM are commercially available but are performed in reference immunohematology laboratories only. Clinically relevant low-affinity antibodies may be removed by washing during the DAT procedure.[32] Washing with low ionic strength solution or with ice-cold saline solution rather than room temperature saline solution may help retain the antibody on the RBCs.[29] Other technical issues may lead to false-negative DAT results. If clinical suspicion for AIHA is strong despite negative DAT results, specialized immunohematology reference laboratories such as those at the American Red Cross offer a DAT-negative AIHA evaluation that tests for IgA, IgM, and low-affinity antibodies.

Importantly, positive DAT results are not necessarily diagnostic. The interpretation and significance of positive DAT results must be correlated with the patient's history, including recent drug or transfusion exposure. Positive DAT results are found in 1 in 1000 to 14,000 healthy donors without hemolysis[42] and in 7% to 8% of hospitalized patients.[30]

Differential Diagnosis

The differential diagnosis of warm AIHA includes other causes of spherocytic anemias; for example, hereditary spherocytosis (HS; see Chapter 16) has many common clinical features. HS is a hemolytic anemia caused by deficient attachments of the lipid bilayer to the underlying membrane skeleton that is most often due to partial deficiency of ankyrin or band 3 or beta spectrin and is less often due to deficiency of alpha spectrin or protein band 4.2. Most diagnoses of HS are made in childhood on the basis of a positive family history or as a result of a similar clinical presentation to AIHA of anemia, jaundice, and splenomegaly. DAT results are always negative in persons with HS. A flow cytometry assay directly targeting the HS molecular defect (the eosin-5′-maleimide binding test) distinguishes spherocytosis due to HS versus other causes, including AIHA.[43,44] Clostridial sepsis,[45] ABO hemolytic disease in neonates (Chapter 3), severe burns or RBC thermal injuries, severe hypophosphatemia, and sometimes the hemolytic anemia associated with Wilson disease[46] (Chapter 11) or congenital dyserythropoietic anemia type 2 are other diseases characterized by spherocytic anemias.

In patients with hemolytic anemia and positive DAT results, several diagnoses should be considered (Box 13-1). Serologic characterization of an autoantibody will help distinguish warm-reacting AIHA, cold-reactive autoantibody syndromes such as CAD and PCH, and mixed-type AIHA. In a patient who has undergone a recent transfusion, positive DAT results may reflect a newly formed alloantibody to donor erythrocytes, indicative of a delayed hemolytic transfusion reaction. Further

TABLE 13-1 Typical Serologic Findings in Autoimmune Hemolytic Anemia

Characteristic	Warm Reactive	Paroxysmal Cold Hemoglobinuria	Cold Agglutinin Disease

characterization of the antibody can distinguish whether it is directed at donor or autologous RBCs.

Drugs can cause hemolytic anemia through an immune or nonimmune mechanism. Drug-induced immune hemolytic anemia (DIIHA) is rare, but more than 100 drugs have been implicated.[47] Common drugs causing hemolytic anemia are piperacillin, cefotetan, and ceftriaxone, and they can mimic AIHA or delayed hemolytic transfusion reactions in some patients. Drug-induced hemolysis requires laboratory demonstration of (1) the patient antibody binding only to RBCs coated with the drug in vitro or (2) the patient antibody supporting deposition of complement on RBCs only when the drug, patient serum containing the antibody, and a source of fresh complement are simultaneously present with RBCs. Hemolysis ceases within days of discontinuation of the drug. Serologic evaluation for DIIHA can be performed by immunohematology reference laboratories; the Blood Center of Wisconsin and the American Red Cross (Southern California Blood Services Region) have particular expertise in this type of evaluation.

Spherocytes are typically found on blood smears in patients with warm AIHA, occasionally in patients with PCH, and rarely in patients with CAD. In other forms of acquired hemolytic anemia, spherocytes are rare on the peripheral blood smear, the DAT results are negative, and these disorders will be distinguished through the history and appropriate laboratory studies. Dark urine or hemoglobinuria may be a feature of paroxysmal nocturnal hemoglobinuria (Chapter 14), which is distinguished by decreased levels of CD55 and CD59 on blood cells as detected by flow cytometry. Peripheral blood erythrocytes derived from the mutant clone lack the capacity to restrict cell-surface activation of the alternative pathway of complement and to block formation of the cytolytic membrane attack complex because of a deficiency of CD55 and CD59, respectively.[48] Microangiopathic hemolytic anemias such as TTP and HUS are characterized by schistocytes and minimal spherocytosis and thus are easily distinguished on a peripheral blood smear. Moreover, thrombocytopenia is a common feature of TTP and HUS, whereas it is uncommon in persons with AIHA unless it is associated with Evans syndrome.

Characteristics of Erythrocyte Autoantibodies

Erythrocyte autoantibodies are generally categorized as "warm" or "cold" based on their thermal reactivity or amplitude (Table 13-1). Warm AIHA is usually caused by IgG autoantibodies that are optimally reactive at 37°C, and CAD is typified by IgM autoantibodies that are optimally reactive at 4°C but react at higher temperatures of 30°C to 37°C as well. Some patients have mixed-type AIHA with both IgG warm and IgM cold autoantibodies. PCH is a form of cold-reacting AIHA caused by IgG autoantibodies; conversely, rare cases of warm AIHA caused by IgM autoantibodies have been described.

Warm-Reactive Autoantibodies

Warm-reactive autoantibodies are maximally reactive at 37°C and typically react with a patient's own RBCs, as well as with all donor RBCs against which they are tested. In some cases a relative or absolute specificity is identified, of which Rh blood group system antigens are the most common. Warm-reactive autoantibodies are usually polyclonal IgG antibodies. The strength of the antiglobulin reaction and the rate of RBC destruction is variable but appears to be influenced by IgG subtype. Four subtypes of IgG antibodies exist and are designated IgG_1, IgG_2, IgG_3, and IgG_4. IgG_1 is the most commonly encountered subclass, either alone or in combination with other IgG subtypes.[49,50] IgG_1 and IgG_3 autoantibodies activate C1 more readily, bind strongly to FcγRI, FcγRII, and FcγRIII, and increase RBC destruction in comparison with IgG_2 and IgG_4 subtypes.[51-53]

DAT results in persons with warm reactive AIHA may be positive for IgG plus complement (67%); IgG only (20%); or complement only (13%).[54] If the autoantibody has been adsorbed by the patient's RBCs in vivo, the serum may not contain detectable free antibody, resulting in a negative indirect antiglobulin test. However, the presence of an IgG autoantibody bound to the erythrocytes may be confirmed by elution of antibodies from the patient's RBCs. Either autoantibodies eluted from the patient's RBCs or those present in serum typically bind to all common RBCs in blood bank test panels. This condition is described as a "panagglutinin" or having no antigenic specificity. The eluate will usually have no serologic reactivity if the only protein coating the RBCs is complement.

In many cases, warm autoantibodies demonstrate a relative specificity for a blood group antigen, most commonly a member of the Rh blood group system.[55,56] The patient's serum or eluate often has broad specificity in the Rh system but may be weaker or nonreactive if tests are performed with cells of rare Rh phenotypes, such as Rh_{null} RBCs that lack the entire Rh complex. Apparent or clear specificity for one of the common Rh antigens (anti-e, anti-E, or anti-c) is occasionally seen, or more commonly a "relative" specificity is demonstrated in which reactivity is stronger with certain Rh phenotypes. Warm autoantibodies in the Kell, LW, Kidd, Duffy, and Diego systems are rare but have also been reported.[57] Autoantibodies against non–blood group antigens are extremely rare and include protein 4.1[58] and band 3.[59] When a relative specificity is identified, transfusion of RBCs lacking the antigen may be useful.

RBC autoantibodies of the IgA class are found in up to 14% of patients with warm AIHA.[60] In cases of DAT-negative AIHA, an isolated IgA autoantibody on the RBCs can occur.[32,41] However, autoimmune hemolysis due to IgA antibodies alone is rare and more commonly acts synergistically with other immunoglobulins (usually IgG) and complement.[61] AIHA due to warm IgM autoantibodies is rare but is associated with severe hemolysis that often fails to respond to standard therapies in both adults and children and may be fatal.[62-64] These cases are difficult to diagnose because the routine DAT does not detect IgM antibodies, and thus misdiagnosis with CAD or PCH may occur if the DAT is positive for C3 only. Serologically, these IgM antibodies appear to have high affinity, resisting RBC dissociation and causing irreversible autoagglutination at 37°C. RBC autoagglutination of the sample should raise the suspicion of IgM autoantibodies, which do not disaggregate despite washing with warm (37°C) saline solution. Dithiothreitol (a reducing agent that inactivates IgM antibodies) does not affect IgG, and treatment of RBCs can be used to define the immunoglobulin type.[62,63] Reference laboratories can distinguish IgM warm autoantibodies by routine tube methods with anti-IgM reagents or by flow cytometry.[65]

Of three cases of pediatric AIHA attributed to warm IgM autoantibodies in contemporary literature, two were fatal despite treatment with corticosteroids, intravenous immunoglobulin (IVIG), RBC transfusions, whole blood exchange transfusions, rituximab anti-CD20 antibody, cyclophosphamide, mycophenolate mofetil (MMF), and cyclosporin A.[62,63] Successful treatment of severe warm-reactive IgM-mediated AIHA with rituximab in a child with common variable immunodeficiency (CVID) has been reported.[64] In patients who have warm IgM-mediated AIHA that does not respond to standard therapies, resulting in severe AIHA, the anti-C5-9 monoclonal antibody eculizumab is now available; however, results of its use in persons with AIHA have not yet been published. Notably, Salama and Mueller-Eckhardt reported 12 cases of warm AIHA associated with non–complement binding IgM autoantibodies that were referred to their reference immunohematology laboratory for serologic evaluation as a result of observed hemolysis that could not be explained by an underlying RBC abnormality; standard DAT results were negative.[66] These patients were treated with blood transfusions and prednisone only, and definitive improvement or remission of hemolysis occurred in 11 of 12 cases; none was fatal.[66]

Cold-Reactive Autoantibodies

Cold-reactive autoantibodies are primarily associated with CAD[67,68] and PCH.[16] Most commonly, CAD affects adults and PCH affects young children. PCH is the most common form of cold-reactive AIHA in children, but postinfectious CAD also occurs in childhood and adolescence, albeit rarely. Both are caused by autoantibodies that bind RBCs optimally at temperatures below 37°C and usually below 31°C. The associated hemolysis occurs through fixation of complement. In general, CAD and PCH may be idiopathic or secondary to an underlying systemic illness such as neoplasm or infection. Cold agglutinins are IgM autoantibodies that primarily cause extravascular hemolysis but can mediate intravascular hemolysis as well, whereas PCH is IgG mediated and causes intravascular hemolysis (Table 13-1).

The pathogenesis of a cold-reactive autoantibody is dependent on its ability to bind host RBCs and activate complement. Although in vitro agglutination may occur maximally at 4°C in vitro, complement fixation by these antibodies occurs at 20°C to 25°C or higher.[69,70] Complement fixation may cause RBC destruction via opsonization by macrophages in the reticuloendothelial system or rarely by direct lysis. With direct lysis, the Fc portion of the immunoglobulin interacts with C1q, the first component of the complement cascade. One IgM molecule is sufficient to bind C1q and activate the propagation from C1 to C9 sequence on the RBC membrane. Such direct lysis results in intravascular hemolysis, leading to hemoglobinemia and hemoglobinuria. Extravascular hemolysis occurs when the complement cascade leaves opsonic fragments of C3 and C4 on the cell surface, which is then ingested by macrophages in the liver or spleen. The ingested RBC may be engulfed entirely or released back into the circulation as a spherocyte after losing some of its membrane, providing an explanation for the observation of occasional spherocytes with IgM-mediated AIHA.

Cold Agglutinin Disease. Cold agglutinins were first described by Landsteiner in 1903, but CAD was not distinguished as a distinct hemolytic anemia until the 1950s.[71,72] CAD is uncommon in children, but when it does occur it is acute and often a result of *Mycoplasma pneumoniae* infection.[16] Postinfectious cold agglutinins can also be seen with Epstein-Barr virus (EBV),[73] varicella,[74] and adenovirus.[75] Postinfectious CAD is caused by polyclonal IgM antibodies, in contrast to monoclonal IgM that is seen classically in older adults with chronic CAD that commonly occurs as a result of an underlying lymphoproliferative disorder.[67,68] CAD typically occurs in the second or third week of illness, and a rapid onset of hemolysis causes the patient to experience jaundice and pallor. Hemoglobinuria and acrocyanosis are not characteristically present in persons with postinfectious CAD. The hemolysis is self-limiting, and the degree of anemia is typically mild to moderate. The cold autoantibody is an IgM with a characteristic anti-I specificity associated with *M. pneumoniae* and anti-i specificity associated with EBV. Patients with postinfectious CAD will demonstrate high (≥256) cold agglutinin titers (although not nearly as high as in the chronic, adult form of CAD, with titers ≥1000), and they will have negative Donath-Landsteiner test results.[16,67] Treatment of postinfectious CAD is supportive and includes keeping the patient warm and using a blood warmer if the degree of anemia warrants RBC transfusion.

In contrast, the chronic form of CAD is seen in elderly patients and is associated with lymphoma, chronic lymphocytic anemia, or Waldenström macroglobulinemia. The autoantibody is of the IgM subtype, is often monoclonal, and is maximally reactive in the cold but has reactivity up to at least 30°C. Patients with the chronic form experience hemoglobinuria from intravascular hemolysis and acrocyanosis of the ears, nose, fingers, and toes from autoagglutination of RBCs in the skin capillaries, particularly in cold weather.[72] Autoagglutination of anticoagulated blood that occurs as the sample of blood cools to room temperature is characteristic and is frequently the first observation made to suggest the diagnosis (Fig. 13-1, C). Autoagglutination can be enhanced by cooling the blood to 4°C and is reversed by warming to 37°C.

Cold-reactive IgM binds to RBCs at lower temperature in the peripheral circulation and causes complement fixation to the RBCs. However, as the blood circulates to warmer regions of body, the IgM dissociates but the complement remains. Thus complement is the only protein detected on the erythrocytes in almost all cases of CAD (postinfectious or chronic). If the RBCs have been collected properly, maintained strictly at 37°C until the serum and red cells are separated, and washed at 37°C, there should be no immunoglobulin detected on the RBCs and no reactivity in the eluate.[76] The majority of IgM cold-reactive autoagglutinins associated with immune hemolysis should have reactivity up to at least 30°C in saline solution or albumin and have a cold agglutinin titer of greater than or equal to 256 when tested at 4°C.[16] Cold agglutinin IgM molecules are typically directed against the I/i RBC antigens. Importantly, the observation of a cold agglutinin alone is not sufficient to diagnose CAD.

Paroxysmal Cold Hemoglobinuria. Historically, PCH was associated with syphilis and was named for paroxysms of constitutional symptoms and hemoglobinuria precipitated by cold temperatures.[77,78] PCH now occurs primarily in children as an acute transient condition following an upper respiratory or viral infection[15,17,78,79] and is detected by the Donath-Landsteiner test. PCH is the second most common form of AIHA in children, with a median age of 5 years.[17,80] The precise incidence and prevalence of PCH in children is unknown. The transient nature of the Donath-Landsteiner antibody, the availability of the Donath-Landsteiner test, and the level of awareness among physicians all affect the recognition and correct diagnosis of PCH.

In children, PCH classically presents within several weeks after a viral infection with the sudden onset of hemoglobinuria, accompanied by fever, pallor, and jaundice. Symptoms of PCH in children are not precipitated by cold exposure, in contrast to the chronic, syphilitic PCH in adults. A specific etiologic agent is not usually identified, but an upper respiratory tract infection precedes the hemolysis in the majority of cases.[17,78] The intravascular hemolysis and a rapidly progressing anemia may also cause headache, abdominal pain, nausea, vomiting, or diarrhea. Hepatomegaly and splenomegaly were reported in up to 25% of cases.[77] The degree of anemia is variable in children but can be severe. Approximately one third of patients have hemoglobin levels of 5 gm/dL or lower at presentation,[17,78] which may further decrease during their clinical course. Reticulocytosis is characteristic, but reticulocytopenia can be observed early in the course of disease and may result from viral suppression of the bone marrow or destruction by the autoantibody. The peripheral blood smear demonstrates RBC agglutination, polychromasia, nucleated RBCs, and occasional spherocytes. The DAT is usually positive for complement only but can be negative for both C3d and IgG. Other laboratory findings include increased levels of lactate dehydrogenase and unconjugated bilirubin, decreased or absent haptoglobin, and increased levels of blood urea nitrogen and serum creatinine.

The Donath-Landsteiner antibody is an IgG biphasic hemolysin that binds to RBCs and fixes complement at lower temperatures but does not cause hemolysis until the complement-coated RBCs are warmed to near 37°C.[80] Between these temperatures, the autoantibody may dissociate. As a result, the DAT is positive with anti-C3 but is usually negative with anti-IgG unless performed at colder temperatures. Donath-Landsteiner antibodies do not interfere in routine pretransfusion and compatibility testing because the autoantibody rarely causes RBC agglutination above 20°C. For the same reason, the antibody screen is usually negative. The autoantibody may agglutinate normal red cells at 4°C, but in contrast to CAD, rarely to titers greater than 64. The Donath-Landsteiner antibody usually has specificity for the P blood group antigen,[16] but other antibody specificities have been reported.[81,82] Many patients with unexplained hemolytic anemia, often with negative DAT results, probably have undiagnosed PCH.[83] The biphasic antibody may be transient and detectable only during the phase of acute hemolysis, and thus in suspected cases the Donath-Landsteiner test should be carried out as early as possible.

To confirm the diagnosis of PCH, the Donath-Landsteiner test can be performed by the hospital blood bank or reference immunohematology laboratory. A fresh sample of blood from the patient must be collected and maintained at 37°C until the serum is separated from the RBCs. Three sets of test tubes, labeled A1-A2-A3,

TABLE 13-2 Positive Donath Landsteiner Test*

	Tube 1 Patient Serum	Tube 2 Patient + Normal Serum	Tube 3 Normal Serum
Tube A Ice bath and then 37°C	+	+	0
Tube B Ice bath only	0	0	0
Tube C 37°C only	0	0	0

+, With hemolysis; 0, without hemolysis.

*The patient's sample should be kept at 37°C until the serum and red cells are separated to avoid the loss of autoantibody by cold autoadsorption prior to testing.

B1-B2-B3, and C1-C2-C3, are used to mix serum with washed group O RBCs that express the P antigen. Tubes 1 and 2 of each set contain the patient's serum, and tubes 2 and 3 contain fresh normal serum that has normal complement levels. One volume of 50% suspension of washed P^+ RBCs is added to each tube, and all the tubes are mixed. After mixing, the three "A" tubes are placed in a bath of melting ice for 30 minutes and then at 37°C for 1 hour. The three "B" tubes are placed in a bath of melting ice for 30 minutes and kept in melting ice for 90 minutes. The three "C" tubes are placed and kept at 37°C for 90 minutes. After the 90 minutes, the tubes are centrifuged and the supernatant fluids are examined for hemolysis.[29] The test is considered positive when the patient's serum, with or without added complement from normal serum, causes hemolysis in the tubes that were first incubated in the melting ice and then at 37°C (tubes A1 and/or A2) and there is no hemolysis in any of the tubes maintained at 37°C (tubes C1 and C2) or in melting ice (tubes B1 and B2) (Table 13-2). Tubes A3, B3, and C3 serve as controls with normal serum and should not demonstrate hemolysis.

PCH usually resolves spontaneously within several weeks and does not recur. Treatment is supportive with transfusion if the anemia is severe. Although the specificity of the Donath-Lansteiner antibody is almost always directed at the P antigen, RBCs lacking the P antigen are rare and not available for urgent transfusion. Most patients requiring transfusion achieve an adequate post-transfusion hemoglobin and hematocrit with P^+ RBCs despite the presumed or documented incompatibility. Although children with PCH do not typically have cold-induced hemolytic symptoms, the patient should be kept warm and the use of a blood warmer for RBC transfusions is prudent despite the lack of data to support this practice. Steroids are often initiated empirically for treatment of AIHA, but because no evidence exists to support their benefit, they can be discontinued once the diagnosis of PCH is confirmed.

Immune Clearance of Sensitized Erythrocytes. The role of antibodies, complement, monocytes, and the reticuloendothelial system in the immune-mediated clearance of RBCs was elucidated more than four decades ago.[25,84-87] In the 1970s, a guinea pig model for AIHA was developed that allowed the study of RBC clearance as a result of antibody or complement.[7,88] IgG-coated erythrocytes were removed predominantly by the spleen, and the amount of surface IgG correlated with the rate of RBC clearance. In contrast, IgM-coated erythrocytes were sequestered and cleared by the liver. Again, the amount of bound IgM correlated with the rate of RBC clearance. These studies established that clearance of IgM-bound erythrocytes was dependent on the interaction of erythrocyte-bound complement fragments with specific receptors on hepatic macrophages.[7] Human monocyte monolayer assays have been developed to correlate in vivo hemolysis with RBC autoantibodies, but these tests have shown limited utility.[89,90] Flow cytometry can also be used to measure the amount of RBC-bound IgG but are also unable to define a clear quantitative threshold to correlate in vivo hemolysis.[91]

Therapy

AIHA is a potentially fatal condition, and the decision regarding treatment depends on the severity and rapidity with which the anemia develops. Because of the relative rarity of the disease, evidence-based treatment of AIHA is limited,[92] particularly evidence regarding pediatric management. No randomized studies and only a few prospective phase 2 trials have been conducted in adults or children. Most reports describe retrospective studies or small series of patients or are single case reports. Comparison of different treatment modalities is challenged by the fact that no formal consensus exists with regard to the definition of complete or partial hematologic response, remission, or refractoriness. Thus most treatment decisions, including whether to provide treatment, are made on the basis of experience and on an individual patient basis. The two major determinants for treatment are the type of antibody involved (IgG vs. IgM mediated) and whether the AIHA is primary or secondary. Hospitalization is almost always required.

Treatment of Acute AIHA

Transfusion Therapy. In the patient with acute, newly diagnosed, or recurrent AIHA, the clinician must first decide whether the patient needs a transfusion immediately. A child who has relatively mild anemia with a hemoglobin level of 9 to 12 gm/dL may require observation alone. If the patient has a moderate to severe degree of anemia with a hemoglobin level of 6 to 9 gm/dL or is symptomatic with lethargy or shortness of breath, or if the rate of decline is precipitous, transfusion therapy is indicated. For patients who have very severe anemia with hemoglobin levels lower than 6 gm/dL, RBC transfusion should be instituted as soon as possible. In cases of warm, idiopathic AIHA, the antibody is typically directed against blood group antigens that are present on most RBCs. Therefore no truly matched RBC units are possible, but transfusion can be safely performed if underlying alloantibodies are excluded. In children and adolescents, clinically significant alloimmunization should only have occurred if they previously underwent transfusion, were pregnant, or received an organ transplant. A patient who has not previously undergone transfusion should have no risk of underlying alloantibodies and thus that lack of risk should be weighed against the risk of withholding transfusion for a time-consuming blood bank alloantibody evaluation in a severely ill child.

In a patient who has previously undergone a transfusion or been pregnant, the presence of an underlying alloantibody must be assessed to provide appropriate RBCs. Patients with AIHA that is associated with warm autoantibodies have an alloimmunization rate between 15% and 45%, but these studies focused primarily on adult patients.[93,94,95] If IgG autoantibodies are demonstrable in the serum, they will typically interfere with routine pretransfusion antibody screening and compatibility testing. IgG antibodies in persons with PCH do not interfere with routine compatibility testing because the autoantibodies do not cause agglutination above 20°C. Autoadsorption or alloadsorption procedures are performed to remove the patient's autoantibody from their serum sample by adsorption with autologous or allogeneic RBCs, thereby allowing identification of any remaining alloantibody in the adsorbed serum.[29] Autoadsorption is generally preferred because removal of antibody activity by adsorption with autologous RBCs confirms that the antibodies removed are autoantibodies rather than alloantibodies. Autologous adsorption is not recommended for patients who have undergone a transfusion within the past 3 months because the blood sample may contain some transfused RBCs that could adsorb alloantibody, even if only a small amount of transfused RBCs are remaining.[96] The patient's RBCs are typically warmed to dissociate some of the bound autoantibodies and then treated with a mixture of enzymes to enhance their capacity to adsorb autoantibody from the serum sample in vitro.[29]

Alloadsorption techniques are indicated when insufficient autologous RBCs are available from a very anemic patient or if the patient has undergone a transfusion in the past 3 months.[96] Allogeneic RBCs used for autoantibody adsorption must lack the antigen(s) against which the alloantibodies react. Because the underlying antibody specificity is usually unknown, a panel of RBCs with different phenotypes must be used to adsorb several aliquots of the patient's serum. RBC selection is based on antigens for which alloantibodies of clinical significance are likely to be present. These antigens include the common Rh antigens (D, C, E, c, and e), K, Fy^a and Fy^b, Jk^a and Jk^b, and S and s. Adsorption techniques are time-consuming and require a minimum of 2 to 3 hours to exclude the presence of alloantibodies but could take up to 4 to 6 hours because each aliquot of serum may need to be adsorbed two to three times to remove all of the autoantibody. Moreover, many hospital blood banks do not perform adsorption techniques and rely on reference laboratories, particularly for allogeneic adsorptions that require a supply of fully phenotyped RBC reagents.

Because adsorption procedures are labor-intensive, some transfusion services choose to prophylactically provide RBCs that are phenotypically matched with the patient's Rh, Kell, and Kidd system antigens rather than searching for new alloantibodies. However, although the most clinically significant antigens may be matched, the potential exists to miss newly developed alloantibodies against other blood group antigens.[93] Shirey and colleagues[94] reported that prophylactic antigen-matched donor RBCs for patients with warm AIHA can obviate the need for adsorption studies in some but not all cases and that provision of extended antigen-matched RBCs is feasible and safe. In 12 of 20 adult patients with autoantibodies (including six with existing alloantibodies), a serologic phenotype was successfully obtained, a total of 149 prophylactic antigen-matched RBC units were transfused, and adsorption studies were avoided on 51 pretransfusion samples. Autoantibodies in the remaining eight patients interfered with determination of a complete RBC phenotype, and adsorption studies were required before transfusion.[94] In both groups, Shirey and colleagues reported expected rises in hemoglobin and hematocrit values and no clinical signs of hemolysis as a result of transfusion, but these signs are probably difficult to assess in patients for whom RBC survival is already expected to be shortened. With increasing availability of molecular methods to type RBCs, which have the potential for a short turnaround period, prophylactic extended antigen-matched transfusions using RBC blood group genotyping is a reasonable option for patients with autoantibodies.[97,98]

Once the blood bank has determined the desired RBC phenotype for a particular patient, the patient's serum will be used to perform crossmatches with the RBC units. If the antigenic specificity is panreactive, the crossmatch will likely identify no units of blood that are fully compatible. Units that are "least incompatible" with the patient's serum are typically provided for transfusion. Thus to prevent a hemolytic transfusion reaction, the most important consideration is to exclude potentially clinically significant alloantibodies before selecting RBCs for the patient.[93,99] In an urgent situation, the clinician must balance the risk of delaying transfusion to complete an alloantibody evaluation against the benefit of an RBC transfusion in a severely anemic patient.[100]

Corticosteroid Therapy. Corticosteroids are the mainstay of treatment for persons with newly diagnosed primary idiopathic warm AIHA (Table 13-3).[101,102] Corticosteroids improve hemolysis in patients with warm AIHA via several mechanisms. Patients who respond to corticosteroids show a decrease in serum antibody concentration, which rises if the dose of prednisone is insufficient.[103] The guinea pig model of AIHA demonstrated that corticosteroids increase the survival of IgG-sensitized RBCs by decreasing sequestration in the spleen.[104] The ability of corticosteroids to suppress sequestration of RBCs by splenic macrophages may be the result of the reduced number of Fcγ receptors observed on peripheral blood monocytes of patients with AIHA during steroid treatment.[105]

In a patient with acute warm AIHA or PCH, intravenous methylprednisolone at a dose of 1 to 2 mg/kg is typically given every 6 hours for 1 to 3 days. In an adolescent, adult guidelines for warm AIHA recommend

TABLE 13-3 Therapy for Autoimmune Hemolytic Anemias

	Acute First Line	Second Line	Third Line	Refractory Cases
Primary warm AIHA	Corticosteroids	Rituximab IVIG Splenectomy	Cyclosporin Azathioprine Mycophenolate mofetil Cyclophosphamide Danazol	Campath-1H High-dose cyclophosphamide
Paroxysmal cold hemoglobinuria	Supportive care	Corticosteroids		Rituximab
Cold agglutinin disease	Avoidance of cold Plasma exchange	Rituximab		Eculizumab Bortezomib

AIHA, Autoimmune hemolytic anemia; *IVIG,* intravenous immunoglobulin.

1 mg/kg/day of oral prednisone or intravenous methylprednisolone,[102] because higher doses result in hypertension, hyperglycemia, acute irritability, or psychoses. Once the patient's hemoglobin level begins to rise and is clinically stable, oral prednisone should be used at a dose of 2 mg/kg/day for children and 1 mg/kg/day for adolescents. High doses of steroids are usually required for 2 to 4 weeks, and then the amount of corticosteroids must be reduced gradually to prevent relapses. For example, once the patient is taking 1 to 2 mg/kg/day of prednisone, a 10% to 20% taper with each dose change is reasonable. Some physicians first switch to an every other day schedule without reducing the total dose by administering a higher dose on even days and a lower dose on odd days. They then taper slowly on the alternate day schedule. Tapering of the corticosteroids is guided by the patient's hemoglobin concentration and reticulocyte count and, to a lesser degree, the DAT results. Most importantly, the steroid taper must be performed slowly over a long period to avoid relapse. When a patient relapses, a very high dose of prednisone is usually required to achieve remission again. Ultimately, the goal is to maintain a stable hemoglobin count with a relatively low dose of corticosteroids and, preferably, an every-other-day regimen. An overall clinical response is achieved in approximately 80% of patients with warm AIHA.[1,106] The total duration of corticosteroid therapy can vary from 3 to 12 months after remission is achieved.

Adverse effects of prolonged corticosteroid use should be considered. These adverse effects include irritability or even psychoses, sleep disturbances, hypertension, hyperglycemia that may require insulin therapy, weight gain, impaired longitudinal growth, and osteoporosis. Patients who are treated with prolonged courses of glucocorticoids should also take calcium and vitamin D supplements and be screened for osteopenia or osteoporosis if their diet and lifestyle place them at particular risk for these conditions.

Intravenous Immunoglobulin. Although IVIG provides potent blockade of the reticuloendothelial system in persons with immune thrombocytopenic purpura (ITP),[107-109] an inconsistent benefit has been shown for patients with AIHA.[110,111,112] The largest cohort of patients studied included 37 cases treated with IVIG in pilot studies from three institutions, combined with a review of 36 cases in the literature, both adult and pediatric.[111] Overall, all but four patients had received or were receiving prednisone therapy at the time of IVIG treatment, and nearly two thirds had received some previous therapy for AIHA. Patients received a range of IVIG doses, including 0.5 gm/kg/day for 5 days to 1 gm/kg/day for 5 to 7 days in the pilot studies, and a range of 0.4 to 2 gm/kg/day for 2 to 5 days in published cases. Overall, 40% had a response as measured by a rise in the hemoglobin level of greater than 2 gm/dL within 10 days of IVIG initiation. Six of 11 pediatric patients (55%) responded to IVIG, but whether they were receiving combined corticosteroid therapy is not reported.[111] Although based on a small number of cases, high-dose IVIG (a 5 gm/kg total dose over 5 days) has been shown to have limited efficacy for the treatment of AIHA.[111,113] In general, IVIG is not considered first-line treatment for AIHA in children, but it may be considered in a patient who is not responding to steroids.

Therapeutic Plasma Exchange. The role of therapeutic plasma exchange (TPE) in patients with warm AIHA is considered a category III intervention by the American Society of Apheresis, meaning it may be beneficial but insufficient evidence exists to establish efficacy.[114] Individual cases have been reported in which plasmapheresis has been efficacious.[115-117] Whether TPE increases the survival of transfused RBCs in patients with severe hemolysis is controversial.[118,119] Because IgG is mostly extravascular and is absorbed onto RBCs at body temperature, TPE may not efficiently remove the RBC autoantibodies. In contrast, IgM is mostly intravascular and binds poorly to RBCs at body temperature, and thus in persons with CAD, TPE can significantly reduce antibody titers, which are higher, particularly in adults.[114] Whether TPE increases the efficacy of RBC transfusions in patients with severe hemolysis is controversial.[118,119] However, plasmapheresis may be considered as a temporizing measure in a severely ill child who has a suboptimal response to RBC transfusion and may not have had time to respond to corticosteroid therapy.

Treatment of Chronic or Refractory AIHA

For a child with chronic or refractory AIHA, more aggressive therapy is often required to maintain a stable hemoglobin and quality of life. Long-term use of corticosteroids is not desirable given the numerous adverse effects.

Several additional therapeutic options should be considered and should be individualized for each patient based on his or her hematologic response and the adverse effects. Splenectomy and rituximab are the only second-line treatments with proven short-term efficacy.

Rituximab. Rituximab is a chimeric human IgG1/K monoclonal antibody specific for the CD20 antigen, which is expressed on B lymphocytes. It induces rapid in vivo depletion of both normal B lymphocytes and lymphoma B cells.[120,121] Its mechanism of action includes complement-mediated cytotoxicity, inhibition of B-cell proliferation, and induction of apoptosis.[120] Because of its clinical efficacy in B-cell lymphoma and its limited toxicity profile, its use has expanded to many autoimmune diseases, as well as benign hematologic diseases.[122,123] Three cohort studies have described the use of rituximab for refractory AIHA in 25 children, all of whom failed to respond to conventional therapies.[19-21] The standard dose of rituximab (375 mg/m^2) was administered weekly for 1 to 6 weeks (a median of four doses). More than 90% of patients had a complete response that lasted 7 to 28 months (a median of 16 months), and only three responders experienced a relapse. All three children who experienced a relapse were treated with another course of rituximab and achieved remission. Numerous single case reports and case series regarding the use of rituximab for AIHA in pediatric patients have been published, and nearly all reported a complete response.[122,124-134] In the largest study by Zecca and colleagues,[19] it was reported that 13 of 15 children (87%) with refractory AIHA responded to treatment with at least a 1.5 gm/dL increase in hemoglobin level observed at a median of 12 days from the time the first dose of rituximab was administered (range, 5 to 72 days).[19] In the responders, a decrease in the absolute reticulocyte count of more than 50% occurred at a median of 21 days (range, 5 to 82 days). Most patients responded within 2 to 4 weeks from the time of the initial dose. Other therapies should be considered if no hematologic response occurs within 2 months.[19,20,124,134] Given the high degree of efficacy of rituximab in treating refractory AIHA in pediatric patients, early use should be considered, and its use should also be considered for patients who respond to steroids but have significant adverse effects. Patients taking corticosteroids before the initiation of rituximab should continue to take steroids until a response to rituximab is clearly established. Although published data that compare rituximab or splenectomy as a second-line therapy are lacking, the trend has been to use rituximab first.

From a safety perspective, rare complications of rituximab include severe infusion reactions, infection, progressive multifocal leukoencephalopathy, and reactivation of hepatitis B and fulminant hepatitis.[123] Untreated hepatitis B infection is a contraindication to rituximab therapy. Because treatment with rituximab causes marked B-cell depletion, with levels remaining low for 2 to 6 months and returning to pretreatment levels after 6 to 12 months,[135] immunizations should be delayed until the B-cell levels return to baseline. After rituximab treatment younger children appear to have a higher risk of transient hypogammaglobulinemia, which can be treated with prophylactic administration of IVIG.[123]

Splenectomy. Splenectomy results in short-term complete and partial response in approximately two thirds of patients.[2,102,136] No long-term follow-up data are available for patients with AIHA who were treated with splenectomy, but approximately 50% of patients will remain in remission for years. In 53 patients with primary and secondary AIHA who underwent splenectomy, 63% had a hematologic remission defined by a hematocrit of greater than 30% without concurrent corticosteroid therapy after a mean follow-up of 33 months.[137] The perioperative risk of splenectomy is relatively low, because most cases can be performed laparoscopically. In a large national study, the mortality and morbidity of laparoscopic splenectomy for hematologic indications was 0.6% and 18%, respectively.[138] Complications included fever (7%), pleural effusion (4%), and actual or suspected hemorrhage (4%).

Because of the risk of postsplenectomy sepsis with encapsulated bacterial organisms (see Chapter 16), prior to surgery children should be immunized with the polyvalent polysaccharide vaccines against *Streptococcus pneumoniae* and *Neisseria meningitides* in addition to the routine infant immunizations against *S. pneumoniae* and *Haemophilus influenzae*. After undergoing a splenectomy, children should also receive penicillin prophylaxis twice a day for at least several years after surgery. Penicillin V potassium, 250 mg twice daily, is recommended for children older than 3 to 5 years, and a dose of 125 mg twice daily is recommended for younger patients. Some clinicians recommend lifelong penicillin prophylaxis because sepsis can occur years after a splenectomy.[139,140] Patients and families should be educated to seek prompt medical evaluation for fever because of the risk of bacteremia or sepsis in a person who has undergone a splenectomy. Relatively recent evidence suggests that splenectomy in patients with AIHA may increase the long-term risk of thromboembolism and pulmonary hypertension[141-144] (also see Chapter 16), and these possibilities should be considered and discussed with the patient and family. The timing of a splenectomy is controversial, because other approaches such as rituximab have become available and are relatively safe.

Alternative Immunotherapeutic Agents. Immunosuppressive and cytotoxic drugs are indicated in patients who do not respond to corticosteroids, rituximab, and splenectomy or for patients who have contraindications to those therapies. Cyclophosphamide, cyclosporine, azathioprine (6-mercaptopurine), and Campath-1H have been used to treat refractory AIHA, but published data on their efficacy are limited to case reports.[145-153] A response to many of these agents may take months, and thus treatment should be continued for up to 6 months before it is considered to have failed.[1] High-dose cyclophosphamide without stem cell rescue for refractory AIHA has induced complete and partial remissions.[154-156] Moyo and colleagues[156] treated nine adult patients who had severe refractory AIHA with cyclophosphamide, 50 mg/kg/day for 4 days. Six patients achieved complete remission with normal hemoglobin levels for their age and sex, and three patients had partial remissions, measured as a hemoglobin level of at least 10 gm/dL without transfusion support. Patients became RBC transfusion–independent after a median of 19 days (range, 15-31 days) after treatment.[156] High-dose cyclophosphamide was well tolerated, but common adverse effects included nausea, vomiting, and transient myelosuppression.

Cyclosporine, 6-mercaptopurine, and MMF (mycophenolate mofetil, Cell-Cept) are additional immunosuppressive agents that have induced clinical remission in some patients with refractory AIHA.[145,148,150,151] By affecting T-lymphocyte function, these agents interfere with autoantibody synthesis. Although cyclosporine has improved the course of AIHA in a few patients with steroid-refractory AIHA, it is not routinely used because of the adverse effects of nephrotoxicity, hypertension, and hirsutism.[145,149] Single-agent therapy with 6-mercaptopurine in pediatric patients with AIHA was reported as part of a case series of autoimmune cytopenias. All seven pediatric patients with refractory AIHA (five cases of primary AIHA and two cases of secondary AIHA) responded, with response defined as an increase in the hemoglobin level of at least 1.5 gm/dL and to a level of 10 gm/dL or greater.[151] The time required to achieve a hematologic response was not reported. The adverse effects of 6-mercaptopurine include leukopenia, thrombocytopenia, and elevated transaminase levels. MMF also inhibits lymphocyte proliferation and was assessed prospectively in a single-center study for adult refractory autoimmune cytopenias.[148] The study included three patients with AIHA that was resistant to high-dose steroids; two of these patients had also responded poorly to IVIG, and one had responded poorly to high-dose cyclophosphamide. All three patients with refractory AIHA responded and achieved a hemoglobin level greater than 10 gm/dL; they were transfusion independent after 4 to 6 months, and the drug was well tolerated. After this response was achieved, MMF was discontinued in one patient and tapered for the other two patients. None had relapsed at a follow-up of 49, 40, and 13 months.[148] Lastly, Campath-1H monoclonal antibodies may improve refractory disease but do not appear to induce a prolonged remission,[152,153] and the adverse effects include significant immunosuppression.

Danazol. Danazol, a semisynthetic androgen, has been efficacious for some adults with AIHA,[157-159] but it has not been studied in children. Synergistic effects of danazol and corticosteroids have been suggested in two studies.[157,159] A rise in the hematocrit level is usually evident within 1 to 3 weeks.[160] The mechanism of action for danazol is not clear, but decreased titers of cell-bound IgG and complement have been reported in patients who had a response.[160] Because of its potential androgenic adverse effects, it is not typically recommended for young females, and the potential liver toxicity makes its long-term use in young children difficult.

Hematopoietic Stem Cell Transplantation. Complete lymphoid and myeloablation with hematopoietic stem cell transplantation (HSCT) is a potential option. HSCT has been explored to treat a variety of autoimmune diseases.[161] Its use in patients with AIHA has been reported with limited success.[162-164] In a study of 36 patients with severe refractory autoimmune cytopenia, two patients underwent allogeneic HSCT and five patients underwent autologous HSCT. The two patients who underwent allogeneic HSCT achieved continuous remission, and of the five patients who underwent autologous HSCT, one died of treatment-related causes, one died of progressive disease, two had no response, and one had a transient response.[162] A single case report describes successful autologous HSCT in a child with refractory AIHA.[163] Despite significant advances in the management of high-dose chemotherapy and HSCT, this treatment option should be reserved for patients with severe life-threatening disease for whom all other therapies have failed.

Treatment Considerations for Cold-Reactive AIHA. In children, CAD typically occurs after an infection, is associated with *M. pneumoniae* or viral infections, and usually only requires supportive care with RBC transfusion (Table 13-3).[15-17,78,79] Importantly, the patient should be kept warm and instructed to avoid cold stimuli. Patients may have a mild, compensated anemia that may not require treatment or transfusions. For persons with moderate to severe anemia, transfusion is necessary. In contrast to the serologic problems encountered in persons with warm AIHA, cold IgM-mediated antibodies do not interfere with pretransfusion testing, and it is usually easy to find compatible donor erythrocytes. If transfusion is indicated, a blood warmer must be used to warm the RBCs as they are infused. In severe cases of cold, IgM-mediated AIHA, plasmapheresis can efficiently remove autoantibodies and improve the clinical course.[114] Exchange procedures should also be performed with an in-line blood warmer for infusion of the plasma replacement.

The treatment of PCH is also supportive with transfusion, because the anemia is often moderate to severe at presentation.[17,78] Although the specificity of the Donath-Lansteiner antibody is directed at the P antigen, P^- donor RBCs are rare, and most patients achieve an adequate posttransfusion hematocrit level with P^+ RBCs. Although cold-induced hemolytic symptoms are not characteristic, the patient should be kept warm and the use of a blood warmer for RBC transfusions is prudent despite the lack of data to support this practice. Steroids are often initiated empirically for treatment of AIHA, but because no evidence exists to support their benefit, they can be discontinued once the diagnosis of PCH is confirmed with the Donath-Landsteiner assay.[80]

Pathogenesis of Autoantibody Formation

The pathogenesis of AIHA is far from clear, and many mechanisms underlying autoantibody production have been proposed. These mechanisms involve autoantigens, the lack of effective presentation of autoantigens, and functional abnormalities of B and T cells.[1] Most evidence suggests that the basis of disease is due to a breakdown in self-tolerance mechanisms toward RBC antigens.

The most common targets of RBC autoantibodies are the Rh blood group proteins, but other blood group antigen specificities, including antibodies directed at glycophorins, band 3, and the RBC anion channel protein have been documented. Cross-reactivity between environmental antigens and autoantigens, termed *molecular mimicry*, has been proposed as the mechanism to explain such autoantibodies.[165,166] However, although deletion of the dominant autoantigen in New Zealand Black mice with AIHA demonstrated a defect in self-tolerance directed at the RBC, the autoantibodies were not specific to one RBC antigen.[167] In New Zealand Black mice with AIHA, this T-helper cell cross-reactivity between the helper-dominant epitope and an exogenous antigen illustrates how specific therapy may be needed to induce immune tolerance.

Self versus nonself discrimination is dependent on induction of tolerance in the thymus and bone marrow by deleting, receptor-editing, or anergizing self-reactive T- and B-cell clones.[168,169] Antigen-presenting cells such as dendritic cells and macrophages present self-antigens to induce T-cell tolerance. One explanation for the lack of effective presentation of autoantigens is that many self-epitopes may be inefficiently processed and presented by antigen-presenting cells. The T cells stay naïve and remain part of the T-cell repertoire rather than being eliminated by the thymus.[170] A genetic predisposition for AIHA has also been proposed involving human leukocyte antigen (HLA) genes that encode the cell surface antigen–presenting proteins. Although no large study has examined the role of HLA genetic polymorphisms and AIHA, an association between the development of AIHA and HLA-B8 and HLA-B27 has been reported.[171,172]

RBC autoantibodies in patients with AIHA are polyclonal with multiple IgG isotypes and, sometimes, IgA antibodies. Sequence analysis of the immunoglobulin gene rearrangements used by B-cell clones from patients with cold agglutinins suggest that typical in vivo polyclonal antigen-driven selection and mutation occurs.[173] Of note, Stahl and colleagues[174] analyzed the self-reactive IgG and IgM antibody repertoires of patients with warm AIHA using quantitative immunoblotting on a panel of whole-tissue extracts representing sources of self-antigens. They demonstrated that the self-reactive IgG repertoires purified from plasma and from RBC eluates did not differ between healthy donors and patients with warm AIHA, whereas the IgM repertoires from patients showed broadly altered patterns of reactivity compared with those of control subjects. The observation that the IgG autoantibodies of patients with warm AIHA are similar to natural-occurring anti-RBC autoantibodies of healthy donors suggests that dysregulation of IgG autoreactivity may be an underlying mechanism for AIHA.

The role of CD4+ regulatory T cells in AIHA has also been studied, because T regulatory cells have been shown to play a key role in immunologic tolerance and in autoimmune diseases.[175] In patients, autoantibodies and activated autoreactive CD4+ T-helper cells that secrete interferon-γ are specific for Rh proteins on the RBC.[166] It has also been demonstrated that T regulatory cells specific for epitopes on the Rh proteins are present in the peripheral blood and spleens of patients with AIHA and that these cells can inhibit T-helper cells by secretion of the suppressive cytokine interleukin (IL)-10.[176,177] This role for regulatory T cells has been corroborated in murine models of AIHA in which C57/Bl6 mice depleted of CD4+CD25+ regulatory T cells developed AIHA at a very high incidence after repeated immunization with rat RBCs.[178] Adoptive transfer of purified CD4+CD25+ regulatory T cells but not CD4+CD25− T cells from immunized mice into naïve recipients prevented the induction of AIHA.

The roles of complement activation and cytokine production in the pathophysiology of AIHA have also been investigated. One study has reported that patients with primary or secondary AIHA may have a deficiency of CD59 expression on their RBCs, which may stimulate abnormal complement activation.[179] Patients with AIHA have also been shown to have high serum levels of IL-1α, IL-2, IL-4, IL-2R, IL-6, IL-10, and IL-13.[180-182] One proposed mechanism is that an imbalance between IL-10 and IL-12 production leads to autoantibody production.[180] Taken together, the mechanism of autoantibody production in persons with AIHA is likely complex and involves polyclonal autoreactive B cells that may be present in healthy persons but expand in genetically susceptible persons or in persons with dysregulation of T regulatory cells or antigen presentation, with subsequent loss of self-tolerance mechanisms.

SECONDARY AUTOIMMUNE HEMOLYTIC ANEMIA

Secondary AIHA can occur as a manifestation of an underlying pathophysiologic disorder. All patients with AIHA should be evaluated for the presence of concurrent autoimmune disease, immunodeficiency, lymphoproliferative disorders, connective tissue diseases, malignancy, infection, and drugs that may induce immune-mediated hemolytic anemia (Box 13-2). In pediatric studies, AIHA was classified as secondary in 24% to 63% of cases.[10-13,183] In the largest and most recent study, 26 of 265 cases (10%) were purely postinfectious, and in 141 of 265 cases (53%), an underlying immunologic disorder was found.[11] Notably, immunologic conditions were discovered after a median follow-up of 2 years in 23 of 49 cases (47%) that were associated with a well-defined infection at time of AIHA presentation. Underlying autoimmune diseases included Evans syndrome in the majority but also included cases associated with autoimmune hepatitis, SLE, thyroiditis, Graves disease, vitiligo, giant cell hepatitis, rheumatic disease, type 1 diabetes mellitus, and Crohn disease. Underlying primary immunodeficiencies included CVID, combined immunodeficiency, autoimmune lymphoproliferative syndrome (ALPS), adenosine deaminase deficiency, Wiskott-Aldrich syndrome (WAS), and HLA class 2 deficiency.[11] The diagnosis of an autoimmune disease such as AIHA in children younger than 1 year of age warrants evaluation for an underlying immunodeficiency. Because many of the diagnostic tests may be affected by corticosteroid or immunosuppressive agents, the sample for laboratory evaluation should be

Box 13-2 **Etiology of Secondary Immune Hemolytic Anemias**

AUTOIMMUNE DISEASE

Evans syndrome
Systemic lupus erythematosus
Autoimmune hepatitis
Autoimmune thyroiditis
Graves disease
Vitiligo
Giant cell hepatitis

DRUGS

Piperacillin, cefotetan, ceftriaxone (most common)

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus; *HLA,* human leukocyte antigen.

sent prior to the initiation of therapy if the patient is clinically stable.

Evans Syndrome

Evans syndrome was first described by Evans and colleagues more than 60 years ago as a disorder of ITP and AIHA, in the absence of known underlying systemic disease.[22] Although the definition of Evans syndrome for many past studies had been restricted to RBC and platelet destruction, the diagnosis can be any combination of ITP, AIHA, and/or autoimmune neutropenia, or immune pancytopenia. Autoantibodies are directed at specific antigens on erythrocytes, platelets, or neutrophils but are not cross-reactive.[184] The exact frequency of Evans syndrome is unknown, but it accounts for 13% to 73% of published pediatric AIHA cases.[11,185-187] A high proportion of overlapping cases of Evans syndrome and ALPS has been suggested.[188,189] Evans syndrome appears to be a disorder of immune regulation with abnormalities in both cellular and humoral immunity,[187,190-192] but the exact pathophysiology is unknown.[193]

Patients may present with AIHA, ITP, and/or autoimmune neutropenia either concurrently or sequentially. Evans syndrome is a chronic disorder, characterized by frequent exacerbations and remissions. Neutropenia occurs in up to 55% of patients at presentation.[22,185-187,192] Often the second cytopenia occurs months to years after the first and may delay the diagnosis. The clinical presentation includes the typical features of hemolytic anemia (jaundice, pallor, lethargy, or dark urine), thrombocytopenia (easy bruising, mucocutaneous bleeding, or petechiae), and/or neutropenia (fever). Physical examination may reveal splenomegaly, hepatomegaly, and/or lymphadenopathy.

Laboratory examination should include a complete blood cell count to determine the presence of cytopenias and a peripheral blood smear not only to evaluate for spherocytes consistent with AIHA but also to exclude other causes. A reticulocyte count, DAT, and total and unconjugated bilirubin levels will aid in the diagnosis, revealing similar findings as in isolated AIHA. Antiplatelet and antineutrophil antibody assays can evaluate for cell-specific autoantibodies in the patient's sera, but these tests may be unreliable, and a negative result does not exclude the presence of the respective autoantibodies. Conversely, anti-HLA antibodies can cause false-positive results. Serum immunoglobulin levels and subclasses should be measured in all patients, because acquired cytopenias can develop in patients with immunodeficiencies.[194,195] Screening tests for SLE and other autoimmune diseases should be strongly considered, and include the measurement of antinuclear antibody, double-stranded deoxyribonucleic acid, and rheumatoid factor. Finally, Evans syndrome can be distinguished from ALPS by determination of peripheral blood T-cell subsets by flow cytometry. Elevation of double-negative (CD4–/CD8–, CD3+, TCRαβ+) T cells is a relatively sensitive screening test for ALPS.[189]

Importantly, Evans syndrome is a diagnosis of exclusion, and by definition, other underlying disorders must not be present.[22] In pediatric cases, the causes of acquired cytopenias to consider in the differential diagnosis include ALPS, SLE, CVID, IgA deficiency, and human immunodeficiency virus/acquired immunodeficiency virus syndrome, all of which require therapies distinct from that for Evans syndrome. Evans syndrome may also develop after autologous or allogeneic stem cell transplantation[196,197] or be associated with Castleman disease.[198,199]

The management of Evans syndrome remains a challenge. No evidence-based studies have established treatment guidelines, but it is reasonable to treat symptomatic cytopenias including moderate to severe anemia, thrombocytopenia with bleeding, or prolonged and/or severe neutropenia (absolute neutrophil count <250 to 500/μL). No randomized, controlled studies have been performed in persons with Evans syndrome, and most published studies include small numbers of patients. RBC transfusions may be needed prior to the initiation of therapy (see the previous discussion of AIHA treatment). The most commonly used first-line therapy is corticosteroids with or without IVIG. In two small studies with a total of 17 children with Evans syndrome, all responded initially to prednisolone, 1 to 2 mg/kg/day, but nearly all experienced a recurrence upon cessation or tapering of the steroid dose.[186,187] Therefore, although steroids are useful in the acute setting, most patients will require adjuvant or alternative therapy to sustain a remission because long-term high-dose steroid use has many significant adverse effects (see the previous discussion of AIHA treatment). IVIG is also a common first-line therapy, particularly for patients who do not respond well to steroids or who experience steroid toxicity. IVIG as a single agent has not been reported for treatment of Evans syndrome; its use has been described in conjunction with steroids or after steroid failure. In a national survey of 42 patients with a median age of 7.7 years, single or multiple courses of IVIG were given with steroids to 40 patients; responses were varied.[185] Nine patients had a complete remission with responses lasting up to 2 years (all of these patients also continued to receive corticosteroids), two patients initially responded but then the disease became refractory after two courses, 24 patients had transient responses lasting up to 4 weeks, and five patients had no response.[185] These limited data suggest that corticosteroids and IVIG have a role as first-line management of Evans syndrome, which is common practice. Repeated courses of IVIG may be helpful for some patients.

Rituximab, a chimeric anti-CD20 monoclonal antibody, is an effective second-line therapy for persons with Evans syndrome, with most published experience in patients who either experienced a recurrence or failed to respond to corticosteroids, IVIG, or other immunosuppressive agents. The efficacy of rituximab was evaluated prospectively in a multicenter study for children with refractory AIHA, including five patients with Evans syndrome.[19] Treatment consisted of weekly rituximab, 375 mg/m^2, for three to four doses. All five patients also received concomitant therapy with steroids, cyclosporin, or azathioprine. All five patients responded with a greater than 1.5 gm/dL rise in hemoglobin level and an increase in platelets from a median of 27×10^9/L before treatment to 140×10^9/L 2 months after treatment. The other immunosuppressants were tapered and discontinued within 25 weeks. Three patients had continued remission with a mean follow-up of 13 months. Two patients experienced a relapse at 7 and 8 months, but both achieved a second remission with a subsequent course of rituximab.[19] In a retrospective study of 17 children with Evans syndrome who also were treated with weekly doses of rituximab—375 mg/m^2 for three to four doses associated with prednisone alone (14 patients) or other immunosuppressive agents—complete or partial remission of at least one cytopenia was achieved in 13 patients (76%).[200] The mean time to complete or partial remission of AIHA and ITP was 1.5 months and ranged from 0.2 to 4 months. Eleven of the 13 patients had sustained responses with a mean follow-up of 2.4 years (range, 0.5 to 7 years), with discontinuation or a greater than 50% tapering of corticosteroids. Depletion of peripheral CD19+ B cells occurred in all 12 patients who were tested, from a baseline mean of 28% to less than 1%, including three nonresponding patients. This depletion lasted 2 to 7 months in five patients who were tested.[200] In both of these studies, therapy was well tolerated. Nearly all patients received replacement IVIG for 4 to 10 months to prevent therapy-induced hypogammaglobulinemia.[19,200] Given the relatively rapid response in most patients who did not respond to corticosteroids, IVIG, and/or other immunosuppressants, along with the safety profile of this drug, rituximab should be considered as second-line treatment early in the course of patients with Evans syndrome who do not respond to steroids. Immunoglobulin levels should be monitored, and replacement IVIG should be administered for low IgG levels.

Additional second-line therapies for Evans syndrome include splenectomy, cyclosporine, MMF (mycophenolate mofetil, Cell-Cept), vincristine, and danazol. Most of the data are anecdotal and difficult to interpret because corticosteroids or other agents were also used. Common second-line agents are cyclosporin or MMF. Combination therapy with cyclosporin (5 to 10 mg/kg/day initially) and prednisone has been successful in patients with refractory Evans syndrome.[201,202] Liu and colleagues[203] found an improved complete response rate in a large series of adult patients with AIHA and Evans syndrome who were treated with prednisone and danazol when cyclosporin was added to the regimen.[203] Several case reports suggest that MMF is well tolerated, can result in reduced use of steroids, and may be used as an alternative therapy for persons with refractory Evans syndrome.[148,204,205]

The role of splenectomy in persons with Evans syndrome is not clearly established. In general, the response rate is lower than in persons with uncomplicated ITP. Splenectomy can achieve improvement of cytopenias, but the response is often transient and relapse occurs in most cases 1 to 2 months later.[185-187] Nonetheless, sustained complete remission has occurred[187] and may also reduce the frequency of relapses and allow lowering of maintenance doses of steroids.[186,187] Given the relatively poor response rates to splenectomy, the inherent risks (see the previous discussion of AIHA treatment), and increasing data and experience with rituximab, splenectomy should be reserved for patients who do not respond to these other second-line therapies.

For patients with severe, relapsing Evans syndrome who do not respond to first- and second-line therapies, remaining options include cyclophosphamide, alemtuzumab, and hematopoietic stem cell transplantation. Cyclophosphamide has induced remission of thrombocytopenia in patients with Evans syndrome at low doses (1 to 2 mg/kg/day oral),[187] intermediate doses,[206] and high doses without stem cell support in an adult with refractory disease.[155] Alemtuzumab (Campath-1H) is an IgG monoclonal antibody directed against the CD52 antigen on T and B lymphocytes. Three patients with refractory Evans syndrome were treated with Alemtuzumab, 10 mg/day for 10 days, and two of three responded initially but subsequently experienced a relapse within 3 months.[153] HSCT has been used to treat severe refractory autoimmune cytopenia.[162,207] In a recent analysis of long-term outcomes of pediatric patients registered in the European Group for Blood and Bone Marrow Transplantation database, of 22 patients who underwent HSCT for refractory autoimmune cytopenias, 11 had Evans syndrome.

Two underwent autologous HSCT; one patient had an initial response and then experienced a relapse, and the other patient had no response. Nine patients received an allogeneic HSCT; five achieved continuous remission, one experienced a relapse, and three died of treatment-related causes.[207] These limited data suggest that a role exists for allogeneic HSCT in the treatment of severe refractory Evans syndrome, but treatment-related toxicity remains high.

Acute Lymphoproliferative Syndrome

ALPS, an inherited disorder of abnormal lymphocyte survival caused by dysregulation of the Fas apoptotic pathway, was first described in 1967.[208] Children with ALPS have defective lymphocyte apoptosis as a result of the failure of developing lymphocytes to undergo Fas-mediated cell death, resulting in an excess of T-cell receptor αβ+CD3+CD4−CD8− T (double-negative T [DNT]) lymphocytes that accumulate in the lymph nodes, spleen, and peripheral blood.[209] This disorder of disrupted lymphocyte homeostasis results in chronic lymphoproliferation, autoimmune disease, and an increased risk of malignancy. The clinical presentation includes childhood onset of chronic lymphadenopathy, splenomegaly, multilineage cytopenias resulting from sequestration and autoimmune destruction, and an increased risk of B-cell lymphoma.[209-211]

This presentation resembled two related mouse strains with lymphoproliferative phenotypes, the *lpr* (lymphoproliferation) and *gld* (generalized lymphoproliferative disease) mice, which were found to have mutations in Fas and Fas ligand, respectively.[212,213] Subsequently, *FAS* mutations were identified in human patients with lymphoproliferative disorders and a failure of lymphocyte apoptosis.[214,215] Laboratory evaluations demonstrated polyclonal hypergammaglobulinemia and expansion of DNT lymphocytes.[209,211] Most patients with ALPS (60% to 70%) carry heterozygous germline mutations in *FAS*, which are inherited in an autosomal-dominant fashion,[216,217] but approximately 10% of *FAS* mutations are acquired.[218,219] Mutations in caspase 8, caspase 10, and neuroblastoma RAS (NRAS) have also been identified in fewer than 5% of patients with ALPS.[220-222] No genetic defect has been found in up to 30% of patients with ALPS.[223]

In 2009, the National Institutes of Health International Workshop for ALPS revised the diagnostic criteria and classification for ALPS,[224] with less focus on a functional apoptosis assay and expanded incorporation of genetic defects and biomarkers. Previously a triad of criteria including chronic nonmalignant lymphadenopathy and/or splenomegaly, increased peripheral DNT cells, and a lymphocyte apoptosis assay defect were used to make the diagnosis of ALPS. Supporting criteria included a family history of ALPS, classic histopathologic features, and autoimmune manifestations. The 2009 revised criteria for ALPS divides diagnostic criteria into two required criteria and six accessory criteria (Box 13-3).[224] For a definitive diagnosis, a patient must meet both required criteria and at least one of the accessory criteria. Required criteria include chronic nonmalignant, noninfectious lymphadenopathy and/or splenomegaly, as well as an elevated level of DNTs (≥1.5% of total lymphocytes or 2.5% of CD3+ lymphocytes). Accessory criteria are divided into primary and secondary. Primary accessory criteria include an abnormal lymphocyte apoptosis assay and the presence of pathogenic mutations in genes of the FAS pathway. Secondary criteria include the presence of elevated circulating biomarkers, characteristic histopathologic features, the combined presence of cytopenias, polyclonal hypergammaglobulinemia, and a family history consistent with ALPS. An abnormal lymphocyte apoptosis assay is no longer considered essential for the diagnosis of ALPS because patients with somatic *FAS* mutations and germline *FASLG* mutation have demonstrated normal results in FAS-induced apoptosis assays.[218,225,226]

Patients with unexplained autoimmune disease, unexplained lymphoproliferation, combined cytopenias, a single cytopenia and hypergammaglobulinemia, or autoimmune disease of a second organ system should be evaluated for ALPS.[227] Recommended screening tests include DNT cell, IgG, and vitamin B12 levels. If screening tests are suggestive of ALPS, molecular testing to distinguish the different subtypes of ALPS should be performed. The current classification system includes five subtypes, categorized by the genetic defect: ALPS-FAS

Box 13-3 **2009 Revised Diagnostic Criteria for Autoimmune Lymphoproliferative Disease***

REQUIRED

1. Chronic (>6 months), nonmalignant, noninfectious lymphadenopathy or splenomegaly or both
2. Elevated CD3+TCRαβ+CD4−CD8− DNT cells (≥1.5% of total lymphocytes or 2.5% of CD3+ lymphocytes) in the setting of normal or elevated lymphocyte counts

ACCESSORY

PRIMARY

1. Defective lymphocyte apoptosis (in two separate assays)
2. Somatic or germline pathogenic mutation in *FAS, FASLG*, or *CASP10*

SECONDARY

1. Elevated plasma sFASL levels (>200 pg/mL) OR elevated plasma interleukin-10 levels (>20 pg/mL) OR elevated serum or plasma vitamin B12 levels (>1500 ng/L) OR elevated plasma interleukin-18 levels (>500 pg/mL)
2. Typical immunohistologic findings as reviewed by an experienced hematopathologist
3. Autoimmune cytopenias (hemolytic anemia, thrombocytopenia, or neutropenia) AND elevated immunoglobulin G levels (polyclonal hypergammaglobulinemia)
4. Family history of a nonmalignant/infectious lymphoproliferation with or without autoimmunity

Modified from Oliveiera JB, Bleesing JJ, Dianzani U, et al: Revised diagnostic criteria and classification for the autoimmune lymphoproliferative syndrome (ALPS): report from the 2009 NIH International Workshop. Blood *116:e35–e40, 2010.*

DNT, Double-negative T cells.

*A definitive diagnosis is based on the presence of both required criteria plus one primary accessory criterion. A probable diagnosis is based on the presence of both required criteria plus one secondary accessory criterion.

(germline homozygous or heterozygous mutations in *FAS*), ALPS-sFAS (somatic mutations in *FAS*), ALPS-FASLG (germline mutations in the FAS ligand), ALPS-CASP10 (germline mutations in caspase 10), and ALPS-U (undetermined genetic defect and *FAS*, *FAS*L, or *CASP10* mutations excluded). The revised classification system considers patients with mutations in caspase-8 (*CASP8*) and NRAS as separate entities given their distinct phenotypes.[224] Patients with *CASP8* mutations present with lymphadenopathy, splenomegaly, marginal elevation of DNTs, and defective FAS-induced lymphocyte apoptosis, but they also show defective T-cell, B-cell, and natural killer–cell activation and are at risk for recurrent bacterial and viral infections.[220] Patients with the *NRAS* mutations may not show elevated DNT cells and may have elevated myeloid cells and a clinical presentation that overlaps with juvenile myelomonocytic leukemia.[224]

The treatment of ALPS is distinct from the treatment of other autoimmune cytopenias. Rituximab and splenectomy are often the treatments of choice for chronic refractory cytopenias such as ITP or AIHA, but these treatments have been shown to have unexpected ALPS-specific toxicities and thus should not be first-line therapies.[223] Patients with ALPS who receive rituximab may experience prolonged and significant hypogammaglobulinemia that may result in prolonged intravenous IgG replacement therapy.[228,229] Splenectomy should be avoided in patients with ALPS because of a very high risk of sepsis after the splenectomy, even with prophylactic antibiotic administration and proper immunizations.[230,231] The typical initial management of patients with ALPS-related cytopenias is immune suppression with corticosteroids. High-dose pulse therapy with intravenous methylprednisolone (5 to 10 mg/kg) followed by oral prednisone (1 to 2 mg/kg) maintenance therapy that is then tapered over several weeks (8 to 12 weeks) has been suggested.[230] IVIG in combination with corticosteroids may be used for severe cases of AIHA, and low-dose granulocyte colony-stimulating factor (1 to 2 μg/kg) two to three times weekly is indicated for patients with isolated chronic neutropenia and associated infections. Subsequent long-term, steroid-sparing therapy is often needed. MMF (CellCept) and sirolimus (rapamycin) are two immunosuppressants that have been relatively well studied and are effective in patients with ALPS.[232-234] More than 80% of patients treated with MMF demonstrate measurable responses for their cytopenias, but MMF does not necessarily improve lymphoproliferation or reduce DNTs.[223,230] Sirolimus, a mammalian target of rapamycin inhibitor, has also been used to successfully treat patients with ALPS,[234] with improved cytopenias, lymphoproliferation, and reduction of DNTs.[230] Despite the successful responses with MMF and sirolimus, the risk-benefit ratio of long-term immunosuppression must be considered for each individual patient with ALPS.

Immunodeficiency

Immune cytopenias can occur in patients with a congenital or primary immunodeficiency as a result of immune dysregulation. Patients with CVID can present with AIHA or ITP.[235-237] In a large cohort of patients, the estimated frequency of AIHA in adult patients with CVID was 5.5% (14 of 252 patients total). CVID was diagnosed before the onset of AIHA in only two patients (11%); the remainder presented with AIHA first, and the diagnosis of CVID was confirmed later.[236] CVID, diagnosed by reduced serum IgG and reduced serum IgA and/or IgM, is characterized by recurrent infections but also an increased risk of autoimmune disease. Autoimmune disease, most commonly ITP and AIHA, develops in approximately 20% to 22% of patients with CVID.[195,238] Treatment of AIHA in patients with CVID is similar to treatment of primary AIHA, with the majority of patients responding to steroids (with and without IVIG in combination), splenectomy, or rituximab.[236,237] However, severe infections have occurred in patients with CVID after treatment with a splenectomy or rituximab.

Patients with WAS may also have immune-mediated cytopenias, including AIHA and ITP. In a large single-institution study, AIHA was diagnosed in 20 of 55 patients (36%) who had WAS by the age of 5 years.[239] Other immunosuppressed populations are also at risk of AIHA, including patients with human immunodeficiency virus[240,241] and patients receiving immunosuppressive therapy after solid organ or hematopoietic transplants.[242,243]

Other Systemic Disorders

A common form of secondary AIHA occurs in patients with SLE.[127,244] Patients with other generalized autoimmune disorders have also been associated with AIHA, including Sjögren syndrome,[245,246] scleroderma,[247,248] dermatomyositis,[249,250] ulcerative colitis,[251,252] Crohn disease,[253,254] and autoimmune thyroiditis.[255] AIHA can also occur in the setting of malignancy, which, in children and adolescents, is associated with acute leukemia,[115,256] lymphoma,[257,258] and myelodysplasia.[259] It is presumed that the underlying immune dysregulation in these systemic disorders causes production of erythrocyte autoantibodies.

Infections

The most common infectious agents identified with childhood AIHA are EBV, mycoplasma, parvovirus, and cytomegalovirus.[11] Varicella,[74] hepatitis C,[260] and rubella[261] have also been documented. The majority of children with PCH have a history of a recent upper respiratory infection or other viral illness with fever, but an infectious pathogen is often not found.[78] *M. pneumoniae* is often associated with anti-I, and EBV is commonly associated with anti-i. Of note, RBCs typically lose i antigen and gain I antigen during the first 18 to 24 months of life.[262] Therefore anti-i autoantibodies do not typically cause significant hemolysis in adults but can be clinically significant in some pediatric cases.[263]

Drugs

Drugs can cause hemolytic anemia through an immune or a nonimmune mechanism. Drug-dependent antibody and autoimmune induction are the primary immune causes, and drug adsorption is the major nonimmune mechanism; all three mechanisms may cause hemolysis.

DIIHA is a relatively uncommon cause of AIHA in childhood, but it is important to recognize because the main therapy is discontinuation of the drug. The three most common drugs causing DIIHA are piperacillin, cefotetan, and ceftriaxone, but more than 130 drugs have been implicated.[47]

Piperacillin is a semisynthetic penicillin that has caused more than 25 reported cases of immune hemolysis, most commonly in patients with cystic fibrosis.[264] In the majority of cases, the hemolysis was acute and severe, and it was fatal in at least one patient.[264-266] In a case series of eight patients, the DAT was positive in all cases, and six of the eight patients demonstrated a serologic profile (positive IgG and C3d DAT, negative antibody screening test, and negative eluate) that is more typical for DIIHA than for any other type of immune hemolysis.[264] Cefotetan is a second-generation cephalosporin that binds firmly to RBCs and can induce IgM or IgG-mediated hemolysis. Cefotetan-induced hemolytic anemia can occur with the first dose and can cause severe and life-threatening episodes.[267-269] Ceftriaxone, a third-generation cephalosporin, is characterized by a rapid acute intravascular hemolysis occurring within minutes to hours after drug administration. The first several cases reported were fatal.[270-273] Arndt and colleagues[274] reported the serologic characteristics of ceftriaxone antibodies in 25 patients with DIIHA. Seventeen (68%) of the patients were children, and the hemolysis was dramatic and severe in pediatric cases. Thirty-six percent of the cases were fatal. The antibodies were primarily IgM, all of the DATs were reactive with anti-C3, and approximately half were reactive with anti-IgG.

Piperacillin, cefotetan, and ceftriaxone-induced immune hemolytic anemia can mimic AIHA and delayed hemolytic transfusion reactions in certain patients, both clinically and serologically. Diagnostic confusion is less common with ceftriaxone because the onset is usually rapid and occurs within hours of receiving the drug. The mimicking effect can be distinguished by testing for the antidrug antibodies, and discontinuation of the drug leads to rapid resolution of the hemolytic anemia and disappearance of the serologic reactions with untreated allogeneic RBCs and the patient's serum.

   This article addresses direct antiglobulin test–negative autoimmune hemolytic anemias, the possible explanations for negative routine serologic findings, and special serologic procedures that may be useful for these clinical scenarios.
47. Garratty G: Immune hemolytic anemia caused by drugs. *Expert Opin Drug Saf* 11:635–642, 2012.
   A comprehensive review of the pathophysiology of drug-induced immune hemolytic anemia (DIIHA), the drugs involved, and the clinical, hematologic, and serologic characteristics of the most common antibodies causing DIIHA.
77. Heddle NM: Acute paroxysmal cold hemoglobinuria. *Transfus Med Rev* 3:219–229, 1989.
   A report of acute transient paroxysmal cold hemoglobinuria (PCH) in children that describes clinical and serologic findings that are distinct from the adult, chronic form of PCH.
78. Gottsche B, Salama A, Mueller-Eckhardt C: Donath-Landsteiner autoimmune hemolytic anemia in children. A study of 22 cases. *Vox Sang* 58:281–286, 1990.
   A study of 22 cases of paroxysmal cold hemoglobinuria in children that compared the action of Donath-Landsteiner antibodies versus cold agglutinins (anti-I) serologically.
80. Eder AF: Review: acute Donath-Landsteiner hemolytic anemia. *Immunohematology* 21:56–62, 2005.
   A comprehensive article on Donath-Landsteiner hemolytic anemia in children that reviews the pathogenesis, clinical presentation, management, and laboratory evaluation of acute paroxysmal cold hemoglobinuria.
92. Crowther M, Chan YL, Garbett IK, et al: Evidence-based focused review of the treatment of idiopathic warm immune hemolytic anemia in adults. *Blood* 118:4036–4040, 2011.
   A review of published data for the treatment of idiopathic warm immune hemolytic anemia in adults that summarizes the findings from one nonrandomized control study and 26 case series.
94. Shirey RS, Boyd JS, Parwani AV, et al: Prophylactic antigen-matched donor blood for patients with warm autoantibodies: an algorithm for transfusion management. *Transfusion* 42:1435–1441, 2002.
   A study that demonstrates that providing prophylactic antigen-matched red blood cells (RBCs) to patients with warm autoantibodies when a complete RBC phenotype can be determined is safe and circumvents or simplifies pretransfusion adsorption studies and compatibility testing.
100. Petz LD: A physician's guide to transfusion in autoimmune haemolytic anaemia. *Br J Haematol* 124:712–716, 2004.
   A resource to clinicians to understand the principles of the compatibility tests performed in patients with autoimmune hemolytic anemia and autoantibodies that interfere with routine pretransfusion testing.
102. Lechner K, Jager U: How I treat autoimmune hemolytic anemias in adults. *Blood* 116:1831–1838, 2010.

Although focused on adults with autoimmune hemolytic anemia (AIHA), this review provides treatment guidelines for acute, refractory, recurrent, or secondary AIHA.

111. Flores G, Cunningham-Rundles C, Newland AC, et al: Efficacy of intravenous immunoglobulin in the treatment of autoimmune hemolytic anemia: results in 73 patients. *Am J Hematol* 44:237–242, 1993.

A combined report of patients treated with intravenous immunoglobulin that included 37 cases that were part of pilot studies at three institutions and a review of 36 cases in the literature.

162. Passweg JR, Rabusin M, Musso M, et al: Haematopoetic stem cell transplantation for refractory autoimmune cytopenia. *Br J Haematol* 125:749–755, 2004.

This study describes the outcome of 36 patients who received hematopoietic stem cell transplantation to treat severe refractory autoimmune cytopenias, including autoimmune hemolytic anemia and Evans syndrome.

185. Mathew P, Chen G, Wang W: Evans syndrome: results of a national survey. *J Pediatr Hematol Oncol* 19:433–437, 1997.

A retrospective review of 42 children with Evans syndrome, including the clinical presentation, treatment, and course.

186. Pui CH, Wilimas J, Wang W: Evans syndrome in childhood. *J Pediatr* 97:754–758, 1980.

An early report describing the clinical presentation and course of a cohort of children with more than one immune cytopenia.

187. Wang WC: Evans syndrome in childhood: pathophysiology, clinical course, and treatment. *Am J Pediatr Hematol Oncol* 10:330–338, 1988.

A study of children with Evans syndrome that describes the clinical presentation, treatment, and course, as well as the associated underlying defects in humoral and cellular immunity.

189. Teachey DT, Manno CS, Axsom KM, et al: Unmasking Evans syndrome: T-cell phenotype and apoptotic response reveal autoimmune lymphoproliferative syndrome (ALPS). *Blood* 105:2443–2448, 2005.

A study that screened 12 children with Evans syndrome by flow cytometric analysis for CD4–/CD8– double-negative T cells and a laboratory based assay for apoptosis mediated by the Fas pathway, showed that half the patients should be reclassified with a diagnosis of autoimmune lymphoproliferative syndrome.

193. Norton A, Roberts I: Management of Evans syndrome. *Br J Haematol* 132:125–137, 2006.

This review focuses on the data to support first-line therapy of Evans syndrome with corticosteroids and intravenous immunoglobulin and, more recently, rituximab, as well as second-line therapies that include immunosuppressive drugs, splenectomy, and hematopoietic stem cell transplant.

200. Bader-Meunier B, Aladjidi N, Bellmann F, et al: Rituximab therapy for childhood Evans syndrome. *Haematologica* 92:1691–1694, 2007.

A study of 17 children with Evans syndrome treated with rituximab alone or in combination with prednisone or another immunosuppressive drug that showed partial or complete remission in 13 patients.

207. Rabusin M, Snowden JA, Veys P, et al: Long-term outcomes of hematopoietic stem cell transplantation for severe treatment-resistant autoimmune cytopenia in children. *Biol Blood Marrow Transplant* 19:666–669, 2013.

A retrospective analysis of 22 children who underwent allogeneic or autologous hematopoietic stem cell transplant for severe refractory autoimmune cytopenia that demonstrated complete and persistent responses in approximately half of the patients.

223. Teachey DT: New advances in the diagnosis and treatment of autoimmune lymphoproliferative syndrome. *Curr Opin Pediatr* 24:1–8, 2012.

This review describes recent insights that provide a better understanding of the genetics and biology of autoimmune lymphoproliferative syndrome.

224. Oliveira JB, Bleesing JJ, Dianzani U, et al: Revised diagnostic criteria and classification for the autoimmune lymphoproliferative syndrome (ALPS): report from the 2009 NIH International Workshop. *Blood* 116:e35–e40, 2010.

Describes the revised diagnostic criteria and classification for autoimmune lymphoproliferative syndrome, including required and accessory criteria.

230. Rao VK, Oliveira JB: How I treat autoimmune lymphoproliferative syndrome. *Blood* 118:5741–5751, 2011.

This article presents an approach to the diagnosis and management of autoimmune lymphoproliferative syndrome, its associated cytopenias, and other complications resulting from infiltrative lymphoproliferation and autoimmunity.

DIAGNOSIS

Management Based on Classification

COURSE AND PROGNOSIS

Course and Prognosis in the Pre-Eculizumab Era

Course and Prognosis in the Eculizumab Era

CONCLUSIONS AND FUTURE DIRECTIONS

Medical textbooks usually include paroxysmal nocturnal hemoglobinuria (PNH) among the hemolytic anemias (as is the case herein). Doing so is not wrong because hemolysis is a defining feature of the disease. However, placing too much emphasis on the hemolytic component of the disease risks obscuring the essence of PNH. Two features distinguish PNH from all other hemolytic anemias. First, and most importantly, the abnormality that underlies the pathobiology of PNH is not confined to the erythrocyte. Rather, PNH is a disease of the hematopoietic stem cell. Secondly, PNH differs from all other intrinsic red cell abnormalities in that the defective process is acquired rather than inherited.

PNH arises as a consequence of somatic mutation of a gene (phosphatidylinositol glycan class A [*PIGA*]) whose protein product is a glycosyl transferase that is an essential component of the biosynthetic pathway that generates glycosyl phosphatidylinositol (GPI) (Fig. 14-1).[1] This moiety serves as the anchoring mechanism for a functionally diverse group of membrane-bound proteins, more than 20 of which are expressed on hematopoietic lineage cells in humans (Box 14-1). The PIG-A mutations that give rise to PNH cause loss of enzyme function, the end result of which is the complete or near-complete absence of expression of all proteins that are GPI-anchored (Fig. 14-2). Among the cellular membrane constituents that are GPI-anchored are the complement inhibitory proteins, CD55 (decay accelerating factor) and CD59 (membrane inhibitor of reactive lysis). It is deficiency of these two proteins that underlies the complement-mediated intravascular hemolysis characteristic of PNH (Fig. 14-3).[2] Despite the loss of all GPI-anchored proteins (GPI-APs) from all hematopoietic lineage cells (erythrocytes, granulocytes, monocytes, lymphocytes, and megakaryocyte/platelets) derived from the *PIGA* mutant stem cell, there is no compelling evidence that deficiency of GPI-APs other than CD55 and CD59 contribute significantly to the pathophysiology of PNH.

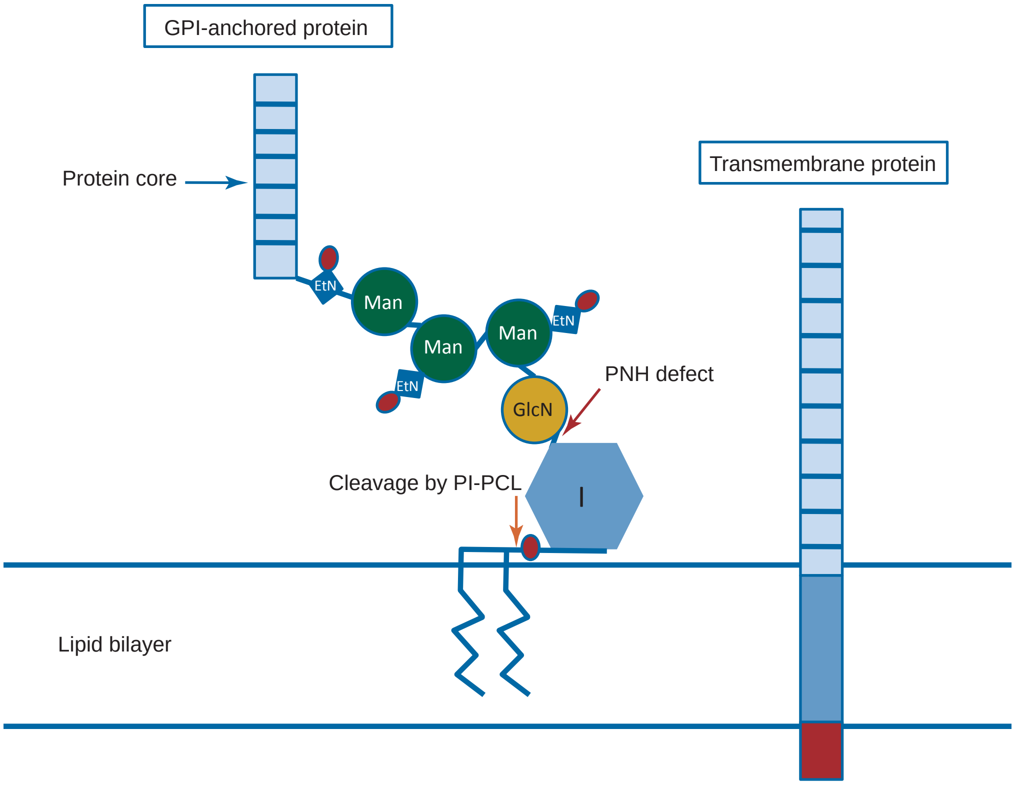

Figure 14-1 Glycosyl phosphatidylinositol–anchored proteins (GPI-APs). The prototypical cellular transmembrane protein *(right)* has an ectoplasmic domain (depicted by the *stacked series of light blue rectangles*, in this case representing the short consensus repeats that characterize proteins that bind complement C3 such as complement receptor type 1 [CD35]), a transmembrane domain composed of a short stretch of ~25 hydrophobic amino acids *(dark blue rectangle)*, and a cytoplasmic tail *(red rectangle)* that usually has signaling properties. In contrast, GPI-APs replace the transmembrane and cytoplasmic domains with a GPI-anchor *(left)*. There are a number of iterations of the GPI-anchor, but the general structure is similar. In the example depicted, two fatty acid residues anchor the inositol *(I)* phosphate *(red circle)* into the lipid bilayer. The glycolipid moiety is attached to the C-terminus of the protein (*light blue stacked rectangles* depicting the short consensus repeats of CD55) by a carbohydrate linker consisting of glucosamine *(yellow circle)* and three molecules of mannose *(green circles)* with ethanolamine *(blue squares)* phosphate *(red circles)* side-chains. The C-terminus of the protein core is covalently bound to the GPI moiety through ethanolamine. A property that distinguishes GPI-APs from transmembrane proteins is release from the cell by treatment with phosphatidylinositol specific-phospholipase C (cleavage site shown by the *orange arrow*). Paroxysmal nocturnal hemoglobin cells are deficient in GPI-APs because *PIGA*, the gene that encodes the glycosyl transferase that mediates transfer of N-acetyl glucosamine to inositol phosphate *(brown arrow)*, is mutant.

In addition to complement-mediated intravascular hemolysis, the other major clinical manifestations of PNH are bone marrow failure and thrombophilia.[3] While the relationship between somatic mutation of *PIGA* and the hemolysis of PNH is understood in detail, the relationship between somatic mutation of *PIGA* (and the consequent deficiency of GPI-APs) and the bone marrow failure and thrombophilia of PNH remain largely speculative. Especially in the case of bone marrow failure, the *PIGA* mutation/deficiency of GPI-APs may not be causal. In fact, the prevailing hypothesis posits that the process that causes the bone marrow failure (proposed as immune attack on the hematopoietic stem cell) selects for the *PIGA* mutant stem cell because absence of one or more GPI-APs bestow a survival advantage by allowing the mutant stem cell either to evade or to better weather immune attack. Whether the thrombophilia of PNH is due to absence of a GPI-AP that is directly involved in regulation of hemostasis/thrombosis (e.g., the receptor for urokinase plasminogen activator) or to indirect consequences of GPI-AP deficiency (e.g., generation of procoagulant microparticles as a result of complement-mediated lysis) remains unresolved.[4]

PNH is a clonal disease (mutant *PIGA* serves as the clonal marker), but it is not a malignant disease in the sense that acute myeloid leukemia (AML) or chronic myelogenous leukemia (CML) are malignant clonal diseases of the hematopoietic stem cell. Unlike AML or CML, in which the mutant clone expands unrelentingly unless antileukemic therapy is initiated, the extent to which the PNH clone expands varies greatly among patients. For example, some patients have small PNH clones that can be detected only by using high-sensitivity flow cytometry to identify GPI-AP peripheral blood cells. Other patients may have large clones in which essentially all hematopoiesis is derived from the mutant stem cell; but even when large, the PNH clone does not have malignant properties in that it does not invade sites outside of the bone marrow, nor does it behave autonomously (i.e., its functional properties appear to be governed by the same regulatory factors as those that control the functional properties normal stem cells), and transformation

Box 14-1 **Glycosyl Phosphytidylinositol–Anchored Proteins Deficient in PNH***

COMPLEMENT REGULATORY PROTEINS†

- CD55 (decay accelerating factor)
- CD59 (membrane inhibitor of reactive lysis)

PROTEINS WITH IMMUNOLOGIC SIGNIFICANCE

- CD58 (lymphocyte function antigen-3)
- CD16b (Fc receptor gamma IIIb)
- CD14 (endotoxin binding protein)

RECEPTORS

- CD87 (urokinase plasminogen activator receptor)
- Folate receptor
- Cellular prion protein *(on resting platelets)*

ENZYMES

- Leukocyte alkaline phosphatase
- Acetylcholinesterase
- 5′-ectonucleotidase

MISCELLANEOUS PROTEINS

- CD24
- CD48
- CD52 (Campath-1)
- CD66c
- CD66b (formerly CD67)
- CD90 (Thy-1)
- CD108 (JMH-bearing protein)
- p50-80, GP109, GP157, GP175, GP500

PNH, Paroxysmal nocturnal hemoglobinuria.
*Partial list.
†Deficiency of complement regulatory proteins underlies the hemolytic anemia of PNH.

into acute leukemia is rarely observed. In fact, an unsolved mystery of PNH is what determines the extent to which the *PIGA*-mutant clone expands. This question is framed by in vitro and in vivo studies demonstrating that mutant *PIGA* alone is insufficient to account for clonal expansion.

More than 25 proteins are involved in the synthesis of the GPI-anchor moiety. Hypothetically, somatic mutation of any of the genes that encode these proteins would produce the PNH phenotype (i.e., deficiency of GPI-APs). Why then is PNH essentially always due to mutation of *PIGA*? The putative answer is based on mathematical probability. Among the genes involved in GPI-AP synthesis, *PIGA* alone is located on the X chromosome.[1] Therefore only one mutational event is required to produce the PNH phenotype because males have one X chromosome, and in females, only one of the two X chromosomes is active in somatic tissues (see Fig. 14-2). Because all other genes involved in GPI-AP synthesis are autosomal, two mutational events would be required to eliminate synthesis of the GPI-anchor and produce the PNH phenotype. Thus, based on mutational frequency ($\sim 1.1 \times 10^{-8}$ per nucleotide position per haploid genome), the probability that deficiency of GPI-APs in PNH would be due to somatically mutated *PIGA* is many orders of magnitude greater than the probability that the deficiency would be due to somatic mutation of both of the alleles of any of the more than 25 autosomal genes involved in GPI-anchor synthesis. Conceivably, germline mutation of one of the alleles of an autosomal gene involved in GPI-AP synthesis could predispose an individual to develop an autosomal form of PNH, and a recent report supports this mechanism as a rare cause of the disease.[5] In essence, however, this situation is analogous to somatic mutation of the X-chromosome gene *PIGA* because the patient was functionally hemizygous for the autosomal gene (*PIGT*) because of the germline mutation of one of the two alleles. This observation adds additional support to the hypothesis that mutant *PIGA* underlies PNH in essentially all cases of PNH because of its unique property among the genes involved in GPI anchor synthesis of structural or functional hemizygosity in somatic tissues.

Understanding the molecular basis of the hemolysis of PNH led to development of targeted therapy in the form of eculizumab (Soliris, Alexion Pharmaceutical), and this treatment has had a major impact on the natural history the disease.[6,7] Nonetheless, management of patients with PNH remains challenging because of the heterogeneous nature of the disease and its close association with bone marrow failure.[8]

This chapter is intended to illuminate for the reader the pathobiology of PNH and to provide guidance on the diagnosis and management of this fascinating disease.

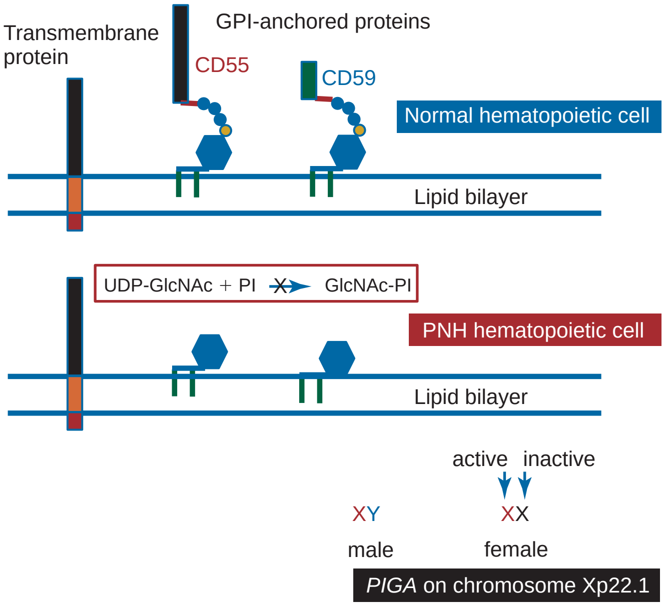

Figure 14-2 The molecular basis of paroxysmal nocturnal hemoglobinuria (PNH). Normal hematopoietic stem cells express both transmembrane and glycosyl phosphatidylinositol–anchored proteins (GPI-APs) *(top panel)*. PNH stem cells express transmembrane proteins normally but fail to express GPI-APs because the first step in synthesis of the anchor is inactivated because the gene *(PIGA)* that encodes the enzyme that is required for transfer of the nucleotide sugar *(UDP-GlcNAc)* to phosphatidylinositol *(PI)* is mutant *(middle panel)*. Of the more than 25 genes involved in synthesis of the GPI anchor, only *PIGA* is located on the X chromosome (all others are autosomal). Location on the X chromosome accounts for the observation that essentially all cases of PNH are due to somatic mutation of *PIGA* because inactivation of only one allele is required to produce the PNH phenotype because males have one X chromosome and in females only one of the two X chromosomes is active in somatic tissues *(bottom panel)*.

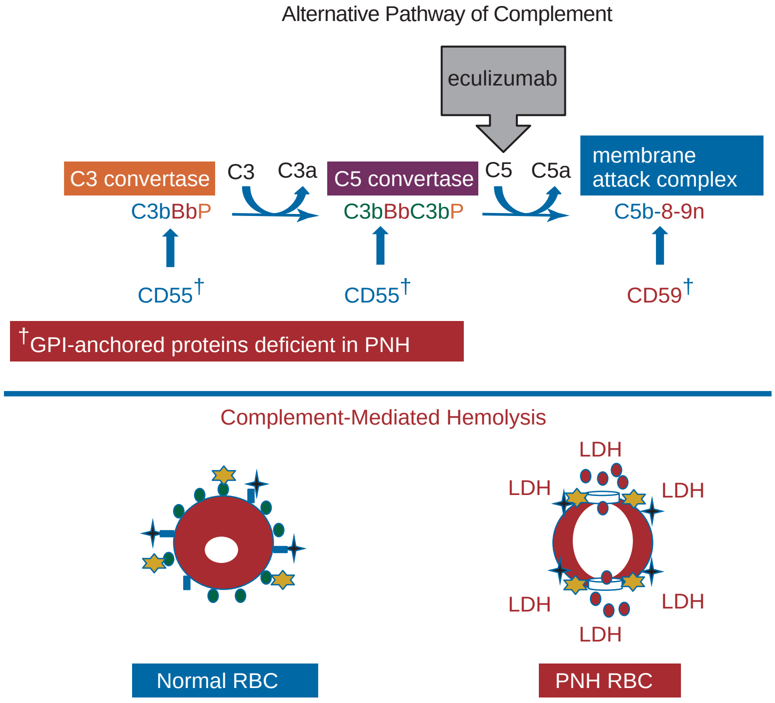

Figure 14-3 Complement and paroxysmal nocturnal hemoglobinuria (PNH). The hemolysis of PNH is due to aberrant regulation of the alternative pathway of complement (APC). The APC is a component of the innate immune system. Unlike the classical pathway of complement that requires a recognition factor such as antibody to activate the pathway, the APC is continuously active. Therefore, safeguards have evolved to protect host cells against APC-mediated injury. In the case of erythrocytes, two glycosyl phosphatidylinositol–anchored proteins, CD55 and CD59, serve this function. Two enzymatic convertases amplify the activity of the APC *(top panel)*. The C3 convertase consists of activated C3 (C3b); activated factor B (Bb), the enzymatic subunit of the complexes; and factor P (formerly called *properdin*). Factor P stabilizes the C3 convertase, allowing each convertase to activate many molecules of C3, and in the process, generate the weak anaphylatoxin C3a. Formation of the C3 convertase is favored at acid pH, explaining the basis of the hemolysis of PNH erythrocytes in acidified serum (Ham's test). The C5 convertase is similar in structure to the C3 convertase except that two molecules C3b are required to position C5 for cleavage by activated factor B (Bb). Many molecules of C5 are cleaved by the C5 convertase, and this process generates many molecules of the potent anaphylatoxin and neutrophil chemoattractant, C5a. Activated C5 (C5b) is the nidus for formation of the membrane attack complex (MAC) of complement consisting of C5b, C6, C7, C8, and multiple molecules of C9. The MAC inserts into the lipid bilayer of the cell, forming a torus that results in osmotic lysis. CD55 blocks the formation and stability of both the C3 and C5 convertases, while CD59 blocks formation of the cytolytic MAC, primarily by inhibiting binding and multiplicity of C9. Eculizumab is a humanized monoclonal anti-C5 antibody that prevents activation of C5 by the C5 convertase. Consequently, the MAC cannot form (and C5a is not generated), accounting for the inhibition of the intravascular hemolysis of PNH. However, eculizumab does not inhibit formation of the C3 convertase, accounting for the opsonization by activation and degradation products of C3 observed in patients with PNH treated with eculizumab. Normal red blood cells *(RBCs)* are protected against APC-mediated injury (*black crosses* represent APC C3 and C5 convertase formation and yellow stars represent MAC formation) by CD55 *(blue ovals)* and CD59 *(green ovals) (bottom panel)*. PNH cells lacking the complement inhibitory proteins CD55 and CD59 undergo complement-mediated lysis, releasing cellular contents including hemoglobin *(red circles)* and lactated dehydrogenase into the plasma.

HISTORY

Comprehensive, scholarly reviews of the history of PNH have been published.[9,10,11,12] The renown Victorian physician, William Gull, may have provided the first published clinical description in 1866, although his brief report failed to distinguish unequivocally PNH from paroxysmal cold hemoglobinuria, which was relatively common at that time because of its relationship to syphilis.[12] In 1882, Paul Strübing of Greifswald, Germany clearly recognized PNH as a distinct entity and undertook prescient experiments designed to test his hypothesis that the nocturnal hemoglobinuria was a consequence of acidification of plasma that occurred when carbon dioxide and lactic acid accumulated because of slowing of respiration during sleep.[9] In 1911, the prolific Dutch physician A.A. Hijmans van den Berg demonstrated that the hemolysis of PNH is caused by a defect in the red cell rather than by the presence of an abnormal plasma factor (as is the case with paroxysmal cold hemoglobinuria that is mediated by the Donath-Landsteiner antibody).[12] Thomas Hale Ham, then in Boston, is credited with discovering, in the late 1930s, that complement mediates the hemolysis of PNH erythrocytes, although it was not until the alternative pathway of complement (APC) was identified and characterized in the mid-1950s by Louis Pillemer of Case Western Reserve University in Cleveland, Ohio, that the basis of Ham's original observations became apparent.[10,11] Notably Ham was on the faculty of Case Western when the alternative pathway was discovered, and Pillemer used PNH erythrocytes in some of his experiments that demonstrated the antibody-independent nature of the alternative pathway and its dependence on magnesium.[10,11] While still in Boston, Ham developed the acidified serum lysis test (Ham's test) that, along with the sucrose lysis test (sugar water test) of Robert Hartmann and David Jenkins of Vanderbilt University in Nashville, Tennessee, were used as the standard diagnostic tests for PNH until being supplanted in the mid-1990s by flow cytometry.[11] Both Hartmann and William Crosby brought attention to the important role that thrombosis (particularly the Budd-Chiari syndrome) plays in the natural history of PNH, and the eminent English physician, John Dacie, and his pupil and colleague S.M. Lewis first systematically characterized the relationship between PNH and marrow failure.[11] Other landmark events in the history of PNH include characterization of the remarkable phenotypic mosaicism, based on complement sensitivity in the late 1960s and early 1970s; demonstration that PNH is a disease of the hematopoietic stem cell in the late 1960s; proof of the clonal nature of the disease in the early 1970s; characterization of the erythrocyte complement defects in the 1970s and 1980s; identification of the complement regulatory proteins that are deficient in PNH in the 1980s; recognition that the membrane proteins that are deficient in PNH are GPI-anchored in the 1980s; identification of *PIGA* as the gene that is mutant in PNH in the 1990s; characterization of the genetic basis of the phenotypic mosaicism in the 1990s; and clinical testing and government approval of the complement C5–inhibitor eculizumab for treatment of the hemolysis of PNH in the first decade of the twenty-first century.[10,11]

EPIDEMIOLOGY

Interpretation of prevalence studies of PNH must take into account the heterogeneous nature of the disease. The blood of patients with PNH is a mosaic of normal and abnormal cells, and the degree of mosaicism varies widely among patients. Those with small PNH clones have few or no symptoms related to hemolysis, and those with clones of less than 1%, detected by high-sensitivity flow cytometry, lack even biochemical evidence of hemolysis. Thus, an argument can be made that asymptomatic patients with small clones do not have clinically significant PNH and should be excluded from prevalence estimates. Others, however, may argue that any patient with flow cytometric evidence of a population of GPI-AP–deficient (GPI-AP–) cells, regardless of clone size, has PNH and should be included in prevalence statistics. Studies of prevalence that address the issue of disease heterogeneity are needed, but by any definition PNH is a rare disease. The prevalence of clinically significant PNH is likely in the order of less than 1 case per 200,000 population, easily fulfilling criteria (less than 1 case per 50,000 population) for classification as an ultraorphan disease.[13]

There is a close association between PNH and aplastic anemia (AA). Environmental factors, drugs, and toxins that cause AA concordantly increase the risk of developing PNH.[14] Although PNH has been reported in all age groups, the peak incidence is in the third and fourth decades of life, similar to that observed for AA. PNH is an acquired disorder, and there is no known inherited risk for developing the disease. A number of cases have been reported in which only one of a pair of identical twins was affected. Inherited mutations in autosomal genes involved in GPI anchor biosynthesis have been identified, but patients with such germline mutations (homozygotes or compound heterozygotes) are characterized by developmental and neurologic abnormalities, including mental retardation and seizures, and by hyperphosphatasia. A patient with mutant *PIGA* died in early infancy because of multiple developmental defects without evidence of hemolysis. Based on this observation and animal studies, *PIGA* mutations whose consequences are sufficiently severe to render the red cells susceptible to complement-mediated hemolysis are embryonic lethal.

MOLECULAR PATHOGENESIS

Careful in vivo studies of red cell survival and in vitro characterization of the complement sensitivity of peripheral blood erythrocytes hinted at the molecular basis of PNH. Red cell survival studies suggested that two populations of erythrocytes coexisted in the peripheral blood of patients with PNH.[15] One population had an abnormally short half-life of about 6 days, whereas the other population had a half-life similar to that of normal erythrocytes (about 60 days). Those observations dovetailed with the results of rigorous experiments that quantified the sensitivity of peripheral blood erythrocytes to complement-mediated lysis, showing that the peripheral blood of PNH patients is a mosaic composed both of erythrocytes that are normally sensitive to complement-mediated lysis and of red cells that are abnormally sensitive to complement-mediated lysis.[16] Together these observations lead to the hypothesis that the abnormal cells were the progeny of a mutant hematopoietic stem cell clone that produced the abnormal erythrocytes.[17] According to this hypothesis, the mutant stem cell coexisted within the bone marrow with normal stem cells from which the erythrocytes of normal complement-sensitivity were derived. Further, that PNH is an acquired rather than an inherited disease implied that the abnormal clone arises as a consequence of somatic mutation rather than germline mutation. In 1970, Oni and colleagues[18] analyzed glucose-6-phosphate dehydrogenase (G6PD) isoforms in both the complement-sensitive and the complement-insensitive erythrocytes of a female PNH patient who was heterozygous for the two G6PD isoforms. The complement-insensitive cells expressed both G6PD isoforms, indicating a polyclonal origin for this cohort. In contrast, the complement-sensitive cells expressed only one G6PD isoform, a finding consistent with monoclonality. These studies provided the first experimental evidence in support of the clonal hypothesis of PNH. In 1969, Aster and Enright[19] reported that a portion of both the platelet and granulocyte populations from patients with PNH was abnormally sensitive to complement-mediated cytolysis. This publication represented another watershed event in the understanding of the origins of PNH because it indicated that the mutation arose in a primitive hematopoietic stem cell that has the capacity to differentiate along myeloid lines. Subsequent studies showed that monocytes are also affected, and, in most patients, affected lymphocytes can be demonstrated. Thus, characterization of PNH contributed substantial early experimental evidence in support of the concept of the pluripotent stem cell.

A defining feature of PNH is phenotypic mosaicism based on sensitivity of the erythrocytes to complement-mediated lysis. This remarkable characteristic was first clearly elucidated by Rosse and Dacie in 1966,[16] and Rosse further refined the analysis in 1973.[20] Using an in vitro test that quantitates the sensitivity of erythrocytes to complement-mediated lysis, three phenotypes of PNH erythrocytes were identified. One of the phenotypes (designated PNH I) was characterized by normal or near-normal sensitivity to complement, whereas another phenotype (designated PNH III) was 15 to 25 times more susceptible to lysis. A third phenotype (PNH II) was of intermediate sensitivity, about 3 to 5 times more susceptible than normal cells. Most patients have a mixture of type I and type III cells, but mosaics of type I, type II, and type III, as well as type I and type II, are also observed. The biochemical and molecular basis of the phenotypic mosaicism of PNH was elucidated by Holguin,[21,22] respectively (see "Membrane Inhibitor of Reactive Lysis" and "Somatic Mutation of PIGA Underlies the Absence of GPI-AP in PNH").

Elegant, rigorous in vitro studies of the aberrant interactions of complement with PNH erythrocytes indicated that two defects underlie the complement-mediated hemolysis that characterized the disease. One abnormality resulted in greater activity of the amplification C3 convertases of the classical and alternative pathways of complement,[23,24] and the other caused PNH erythrocytes to be markedly more sensitive to the cytolytic activity of the membrane attack complex (MAC) of complement.[23,25,26] The basis of these two complement regulatory abnormalities remained a mystery until the 1980s, when PNH erythrocytes were shown to be deficient in both CD55 and CD59 (Figs. 14-2, 14-3).

Paroxysmal Nocturnal Hemoglobinuria and Complement

The chronic intravascular hemolysis that is the hallmark clinical manifestation of PNH is mediated by the APC (see Fig. 14-3).[2] The APC is a component of innate immunity.[27] This ancient system evolved to protect the host against invasion by pathogenic microorganisms. Unlike the classical pathway of complement that is part of the system of acquired immunity and requires antibody for initiation of activation, the APC is in a state of continuous activation, armed at all times to protect the host. The APC cascade can be divided into two functional components: (1) the amplification C3 and C5 convertases and (2) the cytolytic MAC (see Fig. 14-3). The C3 and C5 convertases are enzymatic complexes that initiate and amplify the activity of the APC and ultimately generate the MAC (the MAC is the common cytolytic subunit of the classical and lectin pathways of complement as well as the APC).

Because the APC is primed for attack at all times, elaborate mechanisms for self-recognition and for protection of the host against APC-mediated injury have evolved. Both fluid-phase and membrane-bound proteins are involved in these processes. Normal human erythrocytes are protected against APC-mediated cytolysis primarily by CD55[28,29] and CD59 (see Fig. 14-3).[21,30] These proteins act at different steps in the complement cascade. CD55 regulates the formation and stability of the C3 and C5 convertases, whereas CD59 blocks the formation of the MAC. Deficiency of CD55 and CD59 on the erythrocytes of PNH is the pathophysiologic basis of the direct antiglobulin test–negative, intravascular hemolysis that is the clinical hallmark of the disease.

Decay Accelerating Factor

In 1983, two groups reported that PNH erythrocytes were deficient in CD55.[29,31] CD55, first identified by Hoffmann[32,33] in 1969 and subsequently purified by Nicholson-Weller and colleagues in 1982,[28] is a 70 kD protein that inhibits the formation and stability of the C3 convertases of complement. Thus, the absence of CD55 provided a plausible explanation for the greater binding of activated C3 to PNH erythrocytes that had been observed in in vitro experiments (see Fig. 14-3). Detailed studies, however, demonstrated that CD55 does not regulate the activity of the MAC of complement.[34] Those results implied that PNH erythrocytes were deficient in a second complement regulatory protein that was functionally distinct from CD55.

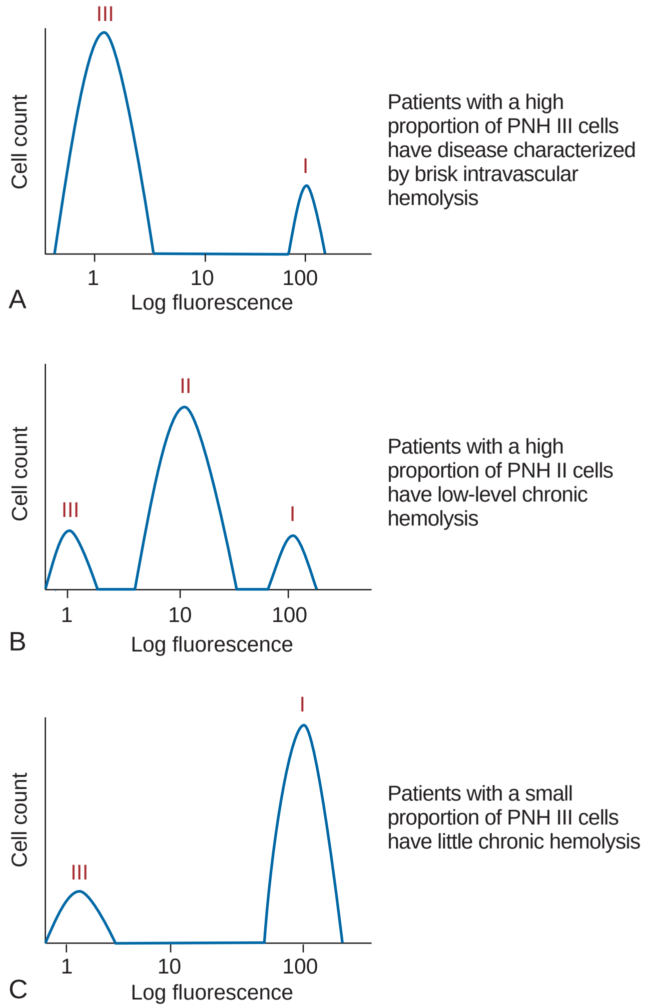
Membrane Inhibitor of Reactive Lysis

In 1989, Holguin and colleagues[30] reported the isolation from normal erythrocytes of an 18 kD protein called *MIRL* (CD59) that protected PNH red cells against complement-mediated lysis. As anticipated, PNH cells were found to be deficient in CD59, and additional studies by those investigators and others demonstrated that CD59 inhibits complement-mediated lysis by blocking the assembly of the MAC.[30,35,36]

By comparing expression of CD55 and CD59 on PNH I, PNH II, and PNH III erythrocytes, the functional basis of the different complement-sensitivity phenotypes was determined.[21] Those studies showed that PNH III cells are completely deficient in both CD55 and CD59, whereas PNH II cells are partially deficient in the two complement-regulatory proteins, and PNH I cells have normal expression. Thus the variability in sensitivity to lysis among the different phenotypes is explained by quantitative differences in expression of CD55 and CD59 (Fig. 14-4). Additional experiments demonstrated that the combined deficiency of CD55 and CD59 was sufficient to explain the enhanced susceptibility of PNH erythrocytes to hemolysis in acidified serum.[37]

Inherited Mutations of CD55 and CD59

Of the two complement regulatory proteins, CD59 is more important than CD55 in protecting cells from complement-mediated lysis in vivo. Antigens of the Cromer-related blood group complex are located on CD55, and rare cases of a null phenotype called *Inab* have been reported.[38] Like PNH cells, Inab erythrocytes are deficient in CD55, but unlike PNH erythrocytes, CD59 expression is normal on Inab red cells.[39] Although Inab erythrocytes bind more activated C3 when exposed to acidified serum,[39] they undergo little or no hemolysis. Further, subjects with the Inab phenotype have no known hematologic abnormalities, and in particular, they have



Patients with a high proportion of PNH III cells have disease characterized by brisk intravascular hemolysis

Patients with a high proportion of PNH II cells have low-level chronic hemolysis

Patients with a small proportion of PNH III cells have little chronic hemolysis

Figure 14-4 Hemolysis in paroxysmal nocturnal hemoglobinuria (PNH) is determined by the erythrocyte phenotype and the size of the clone. Mock, one-color histograms are used to illustrate features of PNH that influence the extent of hemolysis in individual patients. This illustration depicts phenotypes that are observed using anti-CD59 as the fluorescently labeled antibody.

no clinical evidence of hemolysis.[38,40,41] These observations show that isolated deficiency of CD55 does not produce the PNH syndrome.

In contrast, a patient with an inherited, isolated deficiency of CD59 had a syndrome that was indistinguishable from PNH.[42,43] Clinically the patient experienced recurrent episodes of hemoglobinuria, suggesting that CD59 is essential for protecting erythrocytes against complement-mediated lysis in vivo. Recurrent thromboembolic events were also observed in this patient. That patient had normal CD55 expression, but in vitro, his cells were susceptible to hemolysis in acidified serum, implying that CD59 deficiency accounts primarily for the positive Ham's test in PNH.[37]

More recently, Nevo and colleagues reported on five patients from four unrelated families, who presented in infancy with symmetric muscle weakness accompanied by hypotonia and absent deep tendon reflexes involving the legs more than the arms.[44] The neurologic disease was classified as chronic inflammatory demyelinating polyneuropathy. Symptomatic episodes were accompanied by hemolytic anemia characterized by reticulocytosis, negative direct antiglobulin test, elevated serum lactate dehydrogenase (LDH) concentration, and low serum haptoglobin concentration. Leukopenia and anemia were not observed. There was no report of thrombotic complications, although the oldest of the patients in the study was 5 years old. Whole exome sequencing of DNA from one of the patients identified a homozygous missense mutation in the gene that encodes CD59. Subsequent studies identified the same mutation in the other four patients. The mutation segregated with the disease in the families and had a carrier rate of 1 per 66 among Jewish subjects of North-African origin. Cell surface expression of CD59 was absent from the erythrocytes of patients, while expression of CD55 was normal. Together, these studies confirm the importance of CD59 in the pathophysiology of the complement-mediated hemolysis of PNH and suggest an important pathologic role for aberrant regulation of the cytolytic MAC of complement in chronic inflammatory demyelinating polyneuropathy and perhaps other diseases characterized by loss of myelin and axonal integrity.

While the above studies provide interesting insights into the individual function of CD55 and CD59 in vivo, it is important to remember that, in PNH, both proteins (as well as all other GPI-APs on the abnormal hematopoietic clone) are deficient. Therefore it is the combined deficiency of CD55 and CD59 that results in the markedly abnormal susceptibility of the red cells of PNH to complement-mediated lysis.

Congenital Abnormalities of Genes Involved in Glycosyl Phosphatidylinositol–Anchored Protein Synthesis

Germline mutations in genes (*PIGN*, *PIGM*, *PIGO*, *PIGL*, *PIGV*, and *PIGA*) involved in biosynthesis of the GPI-anchor moiety have been reported.[45-50] Notably, hemolysis and bone marrow failure are not observed in patients with germline mutation of GPI-anchor assembly proteins even in the case of germline mutant *PIGA* (see "Epidemiology").[50] The phenotype of patients with germline mutation of genes involved in GPI-AP assembly varies but often involves skeletal anomalies; neurologic abnormalities, including mental retardation and seizures; and hyperphosphatasia.

Paroxysmal Nocturnal Hemoglobinuria and Deficiency of Glycosyl Phosphatidylinositol–Anchored Protein

Beck and Valentine reported in 1951 that neutrophils from patients with PNH were deficient in leukocyte alkaline phosphatase.[51] Thus leukocyte alkaline phosphatase was the first protein found to be deficient in PNH, but the first erythrocyte membrane protein found to be deficient was acetylcholinesterase. In 1959, Auditore and Hartmann[52] presented evidence that the extent of the acetylcholinesterase deficiency correlated with the severity of the hemolysis. More detailed studies by others[53] showed that PNH I red cells had a relatively normal amount of acetylcholinesterase, while PNH III erythrocytes were profoundly deficient. Although the deficiency of acetylcholinesterase plays no role in the abnormal susceptibility of PNH red cells to complement-mediated lysis, ultimately the observations that the red cells lack acetylcholinesterase and that the neutrophils lack alkaline phosphatase provided important insights into the fundamental defect that underlies PNH because both proteins were eventually shown to be GPI-anchored.

If only CD55 or only CD59 were deficient in PNH, it would have been logical to hypothesize that the disease was due to mutations affecting the gene that encodes the particular protein. That PNH cells were deficient in multiple proteins (CD59, CD55, and acetylcholinesterase on red cells and leukocyte alkaline phosphatase on neutrophils), however, eliminated (based on mathematic probability) the possibility that the gene for each protein was mutant. Rather, a more plausible hypothesis was that the PNH defect involved a posttranslational modification common to all of the proteins that are deficient in PNH. In 1984, Medof and colleagues[54] reported that isolated CD55 spontaneously reincorporated into erythrocyte membranes. This property of CD55 had been appreciated by Hoffmann in 1969.[32,33] Working with the butanol-saturated aqueous phase of a crude extract prepared from normal human erythrocyte stroma, Hoffmann showed that the sample contained a factor capable of inhibiting complement-mediated lysis by accelerating the decay of the C3 convertase. He further showed that this substance (that he called *DAF* [CD55] *of stroma* [DAF-S]) had the capacity to reincorporate into red cells and remain functionally active. In 1980, Low and Zilversmit[55] demonstrated that alkaline phosphatase that had been solubilized from cells by butanol extraction exhibited the capacity to bind to phospholipid vesicles. In this case the incorporation was thought to be due to the attachment of a phosphatidylinositol moiety to the enzyme. Subsequent experiments demonstrated that isolated acetylcholinesterase also spontaneously reincorporated into cell membranes. Previous studies had shown that alkaline phosphatase, acetylcholinesterase, and 5′-ectonucleotidase (another protein that is deficient in PNH) were released from the cell surface by treatment with phosphatidylinositol-specific phospholipase C (PIPLC) (see Fig. 14-1). The cumulative work of a number of investigators showed that both the capacity to reincorporate into lipid membranes and susceptibility to cleavage by PIPLC was characteristic of a group of amphipathic membrane proteins that shared the common structural feature of being anchored to the cell surface through a GPI moiety (see Fig. 14-1). The structural link between CD55 and acetylcholinesterase, alkaline phosphatase, and 5′-ectonucleotidase (CD73) was made in 1986 by Davitz and colleagues[56] and Medof and colleagues[57] when those investigators presented evidence that CD55 is a GPI-AP. Subsequent studies confirmed that CD59 is also a GPI-AP.[58] The results of those studies suggested the following paradigm: All proteins that are deficient in PNH are GPI-anchored, and all GPI-APs that are expressed by normal hematopoietic cells are deficient in PNH (see Fig. 14-2). All data to date are consistent with this postulate.

GPI-APs are functionally diverse. In addition to the complement regulatory proteins (CD55 and CD59) and enzymes (acetylcholinesterase, alkaline phosphatase, and 5′-ectonucleotidase [CD73]) discussed above, proteins with a variety of receptor, adhesion, and immune modulatory functions (e.g., FcγRIIIb [CD16b], urokinase plasminogen activator receptor [CD87], endotoxin binding protein receptor [CD14], and LFA-3 [CD58]) are also GPI-anchored. Further a number of proteins whose function is unknown are GPI-anchored. Over 80 eukaryotic proteins have been shown to be GPI-anchored, and approximately 30 of these are found in humans. Currently, the list of proteins deficient in PNH numbers at least 23 (see Box 14-1). This number is less than the total number of GPI-anchored human proteins because PNH is an acquired disease that affects only hematopoietic cells. Thus GPI-APs that are present on somatic tissues other than hematopoietic cells are expressed normally in patients with PNH. Despite the fact that PNH cells lack a number of functionally diverse membrane constituents, the only pathologic component of the disease that is unequivocally causally related to GPI-AP deficiency is the abnormal susceptibility of the erythrocytes to complement-mediated lysis due to deficiency of CD55 and CD59.

The GPI anchor is a complex structure with at least 25 proteins being essential for assembly of the moiety (see Fig. 14-1).[1,59] Hypothetically the PNH phenotype would result if any of these proteins were nonfunctional because if the GPI-anchor is not synthesized, GPI-APs are not expressed. Accordingly, it seemed probable that PNH would be found to be heterogeneous at the molecular level because mutations affecting any one of several genes that encode elements critical for GPI-anchor assembly would produce the disease phenotype. In 1992[60] and 1993,[61] however, two groups published the surprising finding that GPI-protein deficient lymphocyte cell lines derived from different patients with PNH all belonged to the same complementation class (Class A) of GPI-AP–negative cell lines. Additional experiments confirmed that the PNH cell lines had the same biochemical defect as the complementation Class A mutants. Like the Class A mutants, the PNH cell lines failed to synthesize N-acetylglucosaminyl-phosphatidylinositol, the first intermediate in the pathway of GPI-anchor assembly (see Fig. 14-2).

Somatic mutation of PIGA *underlies the absence of GPI-AP in PNH.* A gene that restores normal expression of GPI-APs in the complementation Class A PNH cell lines was identified by Kinoshita and colleagues in 1993.[62,63] As predicted by the studies cited above, the gene, called *PIGA* (for phosphatidylinositol glycan, class A), encodes a protein that is essential for the normal synthesis of GlcNAc-PI (see Fig. 14-2).[62] Subsequently, Takeda and colleagues[63] showed that *PIGA* complements the deficient expression of GPI-APs in PNH lymphoblastoid cell lines and that those cell lines harbored somatic mutations in *PIGA*. Together those studies defined both the biochemical and the molecular basis of the deficiency of GPI-APs in PNH.[64]

Additionally Takeda and colleagues observed that a heterozygous mutation was sufficient to produce the PNH phenotype.[63] As presaged by the studies of Hyman and colleagues,[65] the dominant expression of the somatic mutation was explained when *PIGA* was mapped to chromosome Xp22.1. Because males have a single X chromosome, any functionally significant mutation affecting *PIGA* is expressed. Females are functionally haploid due to X-inactivation. Therefore, somatic mutations in *PIGA* appear dominant when they occur on the active X chromosome (see Fig. 14-2).

Analysis of *PIGA* has revealed that the same mutation can be identified in isolated neutrophils, monocytes, and lymphocytes from individual patients with PNH, confirming that the disease involves the hematopoietic stem cell.[22,63] More than 150 *PIGA* mutations have been identified in affected cells of patients with PNH. Only a few large deletions have been observed.[66,67] The remaining mutations consist of nucleotide substitutions of the missense or nonsense types, or small deletions or insertions that cause frame-shifts and introduce premature termination codons. The mutations are distributed randomly over the entire coding region and at splice junctions. Although some mutations have been observed in more than one patient, most are unique, indicating absence of mutational hot spots in *PIGA*. These observations suggest that clonal selection depends on complete or nearly complete inactivation of PIGA such that expression of GPI-APs is below a critical threshold. Therefore all mutations in PNH cause loss of function (partial or complete) of PIGA.

Studies of *PIGA* mutations have also provided insights into the molecular basis of the phenotypic mosaicism of PNH.[22] Cloned lymphocyte cell lines were established from the peripheral blood of a patient whose erythrocytes were a mixture of PNH I, PNH II, and PNH III cells. Based on expression of GPI-APs, lymphocyte clones with four different phenotypes were observed. Analysis of clones with normal expression of GPI-AP revealed no somatic *PIGA* mutations. In contrast, between lymphocyte clones with two distinct phenotypes based on the pattern of GPI-AP expression (i.e., PNH II and PNH III), four discrete *PIGA* mutations were identified. In the lymphocyte clones with the PNH II phenotype, a missense mutation that changed a highly conserved amino acid was found.[22] This finding suggests that cells with partial expression of GPI-APs (PNH II) are derived from stem cells with mutations that incompletely inactivate PIGA. In the case of the lymphocyte clones with the PNH III phenotype, three separate mutations were identified, each of which was expected to inactivate completely the *PIGA* gene product.[22] Collectively these experiments demonstrate that the phenotypic mosaicism that is characteristic of PNH is a consequence of genotypic mosaicism. Further, because any mutation that completely inactivates PIGA results in PNH III cells, phenotypically identical cells can have different *PIGA* genotypes.

Studies of the pattern of X chromosomal inactivation indicated that, in the female patient with four different *PIGA* mutations, the abnormal clones were not derived from a common ancestor.[22] Further, that each of the mutations was discrete demonstrated that the mutational events occurred independently rather than by clonal evolution. These results demonstrate that PNH is not strictly a monoclonal process and have important implications for the origins of the disease.

Studies of mutational frequency in PNH have produced conflicting results. Some of the disparity is almost certainly due to differences in experimental design and interpretation of data. While an abnormally high mutational rate could contribute to generation of multiple *PIGA* mutant clones, invoking such a process is not necessary to explain the oligoclonality observed in some patients with PNH. Rather, a growth/survival advantage for any *PIGA*-mutant GPI-AP− stem cells likely accounts for the outgrowth of multiple PNH clones. In this sense PNH can be viewed as an example of Darwinian evolution occurring in the bone marrow. According to this hypothesis, hematopoietic stem cells with a randomly acquired mutant *PIGA* exist in the marrow in a quiescent state and become apparent only when deficiency of one or more GPI-APs bestows upon those mutant cells a proliferative or survival advantage. Putatively the selection pressure that is applied to the marrow, such as immune attack, involves one or more GPI-APs such that hematopoietic stem cells with mutant *PIGA* that lack expression of GPI-APs have a survival advantage.

What is the basis of clonal selection and clonal expansion? Despite the progress that has been made in determining the basis of the abnormal sensitivity of the erythrocytes to complement-mediated lysis and the global absence of GPI-APs from hematopoietic cells, an issue that is fundamental to a more complete understanding of PNH remains largely enigmatic. In order for PNH to become clinically evident, the hematopoietic stem cells bearing the mutant *PIGA* must expand so that progeny sufficient to produce symptoms and signs of the disease are generated. In many instances GPI-AP− cells dominate hematopoiesis in patients with PNH, suggesting that the mutant stem cell has a greater proliferative capacity, a survival advantage relative to GPI-AP–sufficient (GPI-AP+) stem cells, or both. That *PIGA* mutations are necessary for the development of PNH is incontrovertible. At issue is whether *PIGA* mutations are both necessary and sufficient to account for the PNH syndrome and whether the *PIGA* mutation provides an absolute or a conditional growth/survival advantage.

PNH differs from monoclonal hematopoietic stem cell disorders such as CML, in which the t(9;21) that generates the fusion protein BCR–ABL is sufficient to account for the proliferative advantage of the mutant cell and in which all normal hematopoiesis is progressively and invariably displaced as a consequence of the uncontrolled proliferation of a transformed clone. In PNH the peripheral blood is a mosaic of normal and abnormal cells and the proportion of GPI-AP+ to GPI-AP− cells varies greatly among patients. Further, that ratio tends to remain fixed over long periods of observations. PNH is, therefore, more aptly characterized as a nonmalignant, clonal process, but the basis of the clonal selection and clonal expansion are incompletely understood.

The oligoclonal nature of PNH[22] suggests that a powerful selection process that is most likely based on phenotype is at work in the bone marrow. According to this hypothesis, stem cells with mutant *PIGA* have an advantage because of some pathologic process (perhaps immune mediated) that involves a GPI-AP. For example an autoimmune process could arise in which the target antigen is a GPI-AP expressed on hematopoietic stem cells. Under those circumstances *PIGA* mutant stem cells (lacking GPI-APs) would escape immune-mediated destruction because the target antigen is absent.

Hematopoietic cells express a relatively large number of functionally diverse GPI-APs (see Box 14-1). Thus absence of all GPI-APs is probably not required for the clonal selection of the mutant stem cells. Rather the selective advantage may be dependent on the absence of a single protein that is GPI-anchored, and the reason for the global deficiency of GPI-AP is that *PIGA* is located on the X chromosome. According to this supposition, an autosomal gene encodes the GPI-AP that is conditionally detrimental (e.g., an antigen targeted for immune destruction or a receptor for a negative growth regulator). Inasmuch as two alleles rather than one must be mutated, the probability of inactivating an autosomal gene through somatic mutagenesis is remote compared to the probability of inactivating an X-linked gene. Therefore stem cells with a deficiency of the detrimental GPI-AP are most likely to arise as a consequence of *PIGA* mutations, as is the case in patients with chronic lymphocytic leukemia treated with Campath1H (anti-CD52).[68] Assuming that the GPI-AP complement regulatory proteins are not the targets of the underlying pathologic process, the hemolytic anemia that is the clinical hallmark of PNH may represent an epiphenomenon that is a consequence of the chromosomal location of *PIGA*.

Although a compelling case can be made in support of the paradigm that the *PIGA* mutation bestows a conditional survival advantage upon the affected stem cell, the hypothesis that the mutant stem cells have an absolute growth advantage must also be considered. Data that both support and challenge this hypothesis can be found.[69-71] The most compelling argument against an intrinsic growth or survival advantage for *PIGA* mutant cells is made by the results of studies using transgenic mice.[72] By using homologous recombination, Kawagoe and colleagues[73] disrupted *Piga* (the murine homologue of *PIGA*). Only mice with a low degree of chimerism survived. Among those animals, the percentage of GPI-AP– erythrocytes ranged from about 1% to 5%. During 10 months of observation, the ratio of GPI-AP– to GPI-AP+ peripheral blood cells did not increase. Studies by others using conditional knockout technology have confirmed these observations.[72] Together these observations indicate that the *PIGA* mutation does not confer an absolute growth or survival advantage.

What Is the Origin of the PIGA-Mutant Stem Cells? Patients with PNH often have more than one *PIGA* mutant clone.[22,74] A tenet of the Darwinian selection hypothesis as it applies to PNH is that *PIGA* mutant hematopoietic stem cells are present during the time when the selection pressure is applied to the bone marrow. *PIGA*-mutant hematopoietic elements have been identified in the peripheral blood and bone marrow of normal volunteers,[75] providing experimental support for this concept, although whether the GPI-AP– cells identified in a normal individual originate from hematopoietic stem cells with mutant *PIGA* has been questioned.[76] While there are experimental data that suggests that the mutational frequency of the gene is abnormally high,[76] that *PIGA* is located on the X chromosome (so that only one allele need be mutated for the phenotype to become apparent) likely accounts primarily for the existence of multiple discrete clones in many patients with PNH.

A Two-Step Model of Paroxysmal Nocturnal Hemoglobinuria Pathogenesis

Studies by Inoue and colleagues suggest that a two-step mechanism may account for the unique pathophysiology of PNH.[77] Those investigators identified two patients whose *PIGA*-mutant cells had a concurrent, acquired rearrangement of chromosome 12. Detailed analysis showed that in both cases, the chromosome 12 rearrangement resulted in disruption of the 3′ untranslated region (3′UTR) of *HMGA2*. As a consequence, a negative regulatory region of the locus was disrupted, resulting in ectopic expression of the gene. *HMGA2* is a member of the high mobility group of proteins (HMGA1a, HMGA1b, HMGA2) that function as architectural transcription factors. HMG members possess no intrinsic transcriptional activity. Instead these nonhistone phosphoproteins orchestrate assembly of stereospecific transcriptional regulatory proteins into enhanceosomes. The cellular targets of *HMGA2* are incompletely defined but appear to include cyclin A and E2F1.

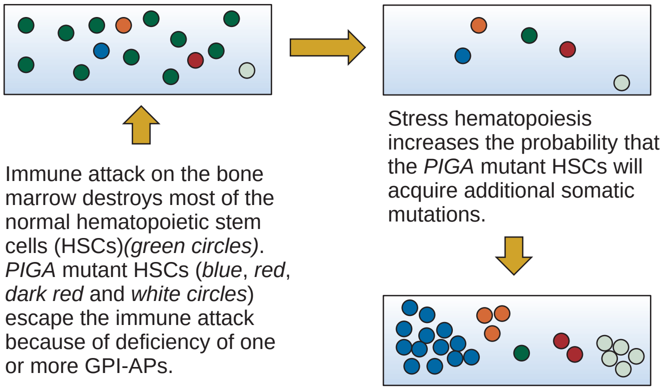
Molecular studies established a causal role for *HMGA2* in benign mesenchymal tumors. Rearrangement of 12q13-15 is observed in these neoplasms, but tumorigenesis does not depend on generation of chimeric proteins derived from fusion of *HMGA2* with specific translocation partners. Rather, clonal expansion induced by *HMGA2* appears to result from deregulated expression of the protein. For the two PNH patients, ectopic expression was a consequence of deregulation of expression caused by truncation of the 3′UTR-containing elements that are the target of microRNA let-7a that negatively regulates HMGA2 expression.[78,79] Additional studies will be required to determine whether aberrant expression of *HMGA2* underlies clonal expansion in PNH patients without structural abnormalities of 12q13-15, but studies by Murakami and colleagues support this hypothesis.[80]

Recently, Sugimori and colleagues reported concurrent mutation of *JAK2* (*JAK2V617F*) in three patients with PNH.[81] This mutation drives clonal expansion in myeloproliferative disorders including polycythemia vera, primary myelofibrosis, and essential thrombocytosis. Thus the JAK2V617F mutation likely contributes to clonal expansion of hematopoiesis in this subgroup of patients with PNH.

In contrast to a disorder characterized by cellular transformation and malignant cellular growth, PNH manifests many of the characteristics of a benign tumor because there is limited expansion of *PIGA* mutant clones (the peripheral blood of patients is a relatively stable mosaic of normal and abnormal cells), *PIGA* mutant cells respect tissue boundaries (there is no invasion of nonhematopoietic tissues), *PIGA* mutant cells respond appropriately to signals that normally regulate hematopoiesis (function is not autonomous), and transformation into acute leukemia occurs rarely (PNH is not a premalignant condition).[6,82] The studies of Inoue and colleagues[77] suggest the concept of PNH as a benign tumor of the bone marrow with aberrant expression of *HMGA2* acting in concert with mutant *PIGA* (and the consequent deficiency of GPI-APs) to produce the proliferative phenotype that underlies clonal expansion. These studies did not define whether (or if) the aberrant expression of *HMGA2* works additively or synergistically with mutant *PIGA* to produce the proliferative phenotype.

The findings of Inoue and colleagues[77] provide new insights into the etiology of the nonmalignant clonal hematopoiesis of PNH. These studies support a two-step process consisting of (1) clonal selection based on phenotype (i.e., GPI-AP deficiency resulting from mutant *PIGA*) and (2) clonal expansion as a consequence of a second somatic mutation that bestows an additional growth/survival advantage. Clonal selection may induce exit of *PIGA* mutant stem cells from a dormant state, thereby favoring acquisition of the second mutation that underlies clonal expansion. The variable expansion of *PIGA*-mutant clones among patients and among mutant clones in the same patient could be explained by heterogeneity involving the second genetic event that partners with mutant *PIGA*. According to this hypothesis, mutant *PIGA* is promiscuous with respect to the second mutant gene with which it partners. But the benign nature of PNH suggests that genes involved in clonal expansion of *PIGA* mutant stem cells are different from those that underlie malignant clonal diseases such as acute leukemia. In fact, concurrent mutation of *PIGA* with mutation of genes that drive tumorigenesis may be synthetically lethal, accounting for the low incidence of transformation of PNH into a malignant clonal process such as acute leukemia.

In summary, the basis of the clonal dominance in PNH is incompletely understood, however, available evidence supports a two step-model of pathogenesis (Fig. 14-5). Step 1 of this model is clonal selection. In this case, a loss-of-function mutation affecting *PIGA* causes deficiency of GPI-APs on affected stem cells. These mutant stem cells have a relative survival advantage in the setting of immune-mediated bone marrow failure (e.g., AA) (see Fig. 14-5). Clonal expansion, step 2 of the PNH pathogenesis model, is envisioned as a consequence of clonal evolution in which mutation of a second gene, working in concert with the consequences of mutant *PIGA*, bestows upon the double mutant stem cell an absolute proliferative/survival advantage (see Fig. 14-5).[77] The extent of expansion of a particular mutant clone and the dominance of one *PIGA* mutant clone in the presence of other *PIGA* mutants may be mediated by the nature of the second event that may be molecularly heterogeneous (see Fig. 14-5). Alternatively, a limited number of second mutations may partner with mutant *PIGA,* and the extent of clonal expansion may be determined by how the second mutation affects gene function.



Immune attack on the bone marrow destroys most of the normal hematopoietic stem cells (HSCs)*(green circles)*. *PIGA* mutant HSCs (*blue*, *red*, *dark red* and *white circles*) escape the immune attack because of deficiency of one or more GPI-APs.

Stress hematopoiesis increases the probability that the *PIGA* mutant HSCs will acquire additional somatic mutations.

The extent to which each *PIGA* mutant HSC expands depends upon the effects of the second somatic mutation on the proliferation/survival characteristics of the affected cell.

Figure 14-5 Hypothetical model for selection and expansion of *PIGA*-mutant, glycosyl phosphatidylinositol–anchored proteins–deficient (GPI-AP–) hematopoietic stem cells. A two-step model is proposed. Step 1 is clonal selection based on phenotype (i.e., deficiency of GPI-APs due to mutant *PIGA*. Step 2 is clonal expansion based on acquisition of additional somatic mutations that provide a growth/survival advantage to the *PIGA* cell. The extent to which the *PIGA* mutant clone expands depends upon the effects of the second mutation on the proliferative and survival characteristic of the GPI-AP– cell.

CLINICAL MANIFESTATIONS

Most commonly, patients with classic PNH complain initially of malaise, lethargy, fatigue, and asthenia (Box 14-2). Other frequently reported symptoms include dyspnea, abdominal pain, and chest pain. PNH usually begins insidiously because clinically apparent hemoglobinuria is the presenting symptom in only about 25% of cases.[6,83] The disease course is chronic with a generally stable clinical pattern in a given individual. The illness ranges in severity from a mild, clinically benign process to a chronically debilitating, potentially lethal disease. The diagnosis is made most frequently in the third to fifth decades of life,[6,82,84] but PNH is also encountered in childhood[85] and in old age.[6,82,84] Both genders are affected with perhaps a slight female predominance, and PNH has been described in many racial groups. The disease has no familial tendency. A patient with complete global deficiency of GPI-AP has not been reported, suggesting that germline mutations of PIGA are embryonic lethal. This hypothesis is supported by the lack of success in producing a homozygous or hemizygous knockout mouse using targeted mutation of Piga.[73] Observations in humans also support the hypothesis. An X-linked lethal disorder characterized by cleft palate, neonatal seizures, contractures, and central nervous system structural malformations was investigated using whole exome sequencing.[50] In that case, a germline mutation of PIGA was identified, but the PNH phenotype was not observed. In vitro studies indicated that the mutant PIGA had partial function, thereby accounting for the absence of hemolysis. Similarly, two unrelated kindreds with germline mutations in the

LABORATORY ABNORMALITIES

- Cytopenias (anemia, thrombocytopenia, leukopenia, pancytopenia)
- Evidence of intravascular hemolysis (elevated lactate dehydrogenase, elevated indirect bilirubin, low haptoglobin)
- Flow cytometry demonstrates deficiency of glycosyl phosphatidylinositol–anchored protein on a portion of red cells, granulocytes, and monocytes
- Iron deficiency
- Hemosiderinuria

*A presenting symptom in approximately 25% of cases.

†May involve an unusual site (skin, splanchnic veins [Budd-Chiari syndrome], cerebral veins).

promoter of the autosomal gene PIGM were identified.[46] Homozygotes were characterized by a propensity toward venous thrombosis and seizures, but clinically significant hemolysis was not observed. The lack of hemolysis was explained by flow cytometric analysis that showed only partial deficiency of GPI-anchored complement regulatory proteins on the red cells. Together, these observations indicate that germline deficiency of GPI-APs sufficient to produce the PNH phenotype is not compatible with life (see "Congenital Abnormalities of Genes Involved in Glycosyl Phosphatidylinositol–Anchored Protein Synthesis"). As previously noted (see "Inherited mutations of CD55 and CD59"), patients with an inherited deficiency of CD59 have a syndrome that includes complement-mediated intravascular hemolysis similar to that observed in PNH due to mutant PIGA, but other GPI-APs were expressed normally in these patients.[43,44] In addition to complement-mediated intravascular hemolysis, the group of patients with homozygous germline mutation of CD59 of Jewish North-African origin described by Nevo and colleagues presented with signs and symptoms of chronic inflammatory demyelinating polyneuropathy.[44]

Hemoglobinuria

Although essentially all patients with classic PNH have episodes of hemoglobinuria some time during their illness, this defining symptom is reported as part of the initial evaluation in only one quarter of all patients. Whether nocturnal hemoglobinuria is the result of an increase in the rate of hemolysis that occurs during sleep or simply the result of overnight accumulation of urine in the bladder is unresolved. Hemoglobinuria is not related to time of day, however, because the pattern can be reversed if the patient is kept awake at night and allowed to sleep during the day. In patients with nocturnal hemoglobinuria, the urine is usually darkly discolored in the morning and clears gradually over the course of the day (Fig. 14-6, *A*). When hemolysis is intense, however, hemoglobinuria persists throughout the day.

The cause of the nocturnal exacerbation (if it truly exists) is poorly understood. Retention of carbon dioxide, causing a slight fall in plasma pH sufficient to activate the APC, is a possible explanation, but this hypothesis has been challenged.[86] That the first voided urine of the morning is representative of the concentrated filtrate that has accumulated and remained in the bladder over a prolonged period of time (i.e., during the period of sleep) likely contributes to the impression that hemolysis worsens overnight.

Episodic Hemolysis

In addition to the sleep-related pattern, most patients with classic PNH experience irregular exacerbations of hemolysis and hemoglobinuria. Paroxysms can be precipitated by a variety of events including infections (even minor types), surgery, transfusions, iron supplementation, vaccinations, and menstruation. Attacks of hemoglobinuria are unrelated to cold exposure, thus distinguishing PNH clinically from paroxysmal cold hemoglobinuria.

Mild hemolytic episodes often pass without significant symptoms, but more severe attacks may be associated with substernal, lumbar, or abdominal pain, together with malaise and headaches. The abdominal pain may be colicky and last for 1 to 2 days. The abdomen may be painful to palpation, especially in the left upper quadrant, with guarding and rebound tenderness. The back pain resembles that noted in patients with other types of intravascular hemolysis (such as in an ABO incompatible transfusion reaction) and is most severe in the lumbar region. Headaches may be excruciating and sometimes last for days.

Paroxysmal Nocturnal Hemoglobinuria and Bone Marrow Failure

Although the marrow of patients with classic PNH appears fairly normal morphologically, numerous in vitro studies have shown that the growth characteristics of marrow-derived stem cells are aberrant.[14,71,87] Moreover, when stem cells are sorted into GPI-AP– and GPI-AP+ populations, compared to the GPI-AP+ population, the growth characteristics of the GPI-AP– population more closely approach those of normal control cells.[71] One plausible explanation for this observation is that the GPI-AP– cells are relatively protected from the pathophysiologic process that mediates the marrow injury, thereby providing a basis for natural selection of the *PIGA* mutant clone. In this view of PNH, outgrowth of the *PIGA* mutant clone is seen as an example of Darwinian evolution occurring within the microenvironment of the marrow. Although intellectually appealing, rigorous experimental support for this hypothesis is lacking.

Using high-resolution flow cytometry with the capacity to detect less than 0.003% GPI-AP– erythrocytes and

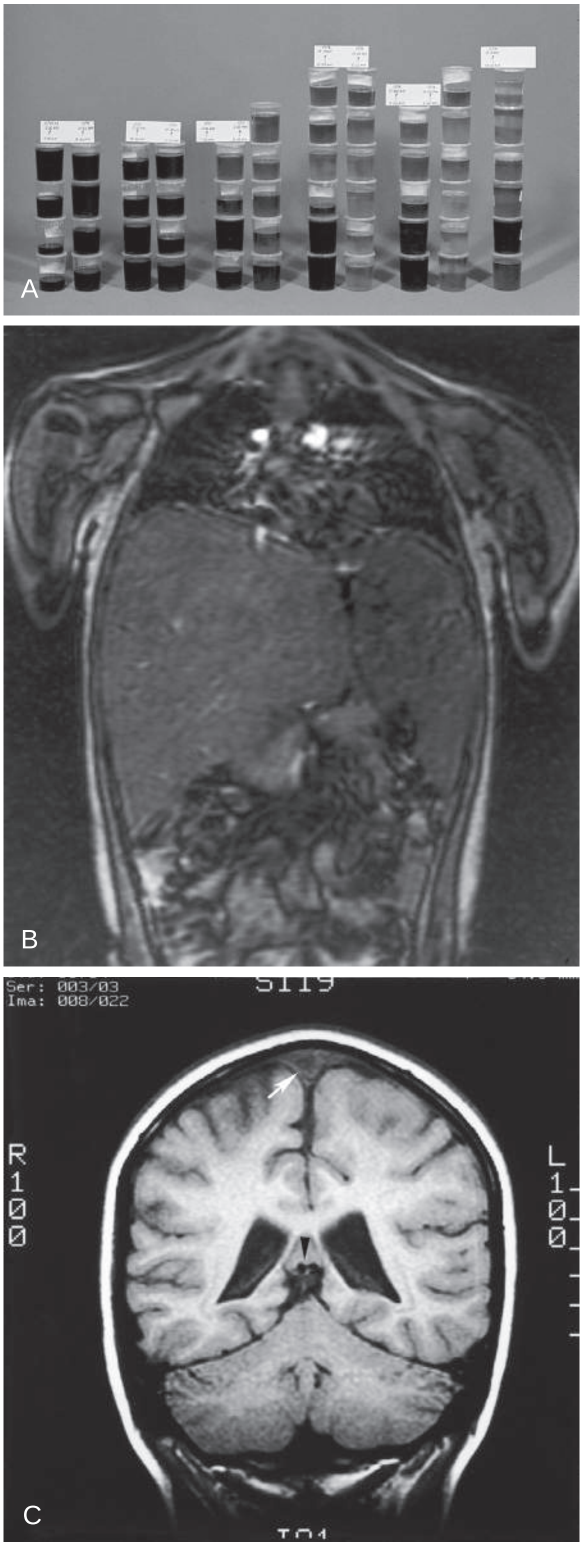

Figure 14-6 Clinical manifestations of paroxysmal nocturnal hemoglobinuria (PNH). **A,** Hemoglobinuria produced over a period of several days, with urine samples ranging in appearance from normal yellow to black. **B,** Massive hepatosplenomegaly that developed in a 14-year-old patient with PNH and Budd-Chiari syndrome. **C,** A fatal superior sagittal sinus thrombosis that developed in a 16-year-old girl with PNH. In this T1-weighted coronal image at the level of the posterior internal cerebral veins, the normally expected black flow signal void in the superior sagittal sinus *(white arrow)* is replaced with an intermediate signal as a result of the thrombus. This appearance contrasts with the normal black venous flow void that is preserved in the internal cerebral veins *(black arrowhead). (A, Courtesy of Dr. Wendell Rosse; C, Courtesy of Drs. Frank Keller and Jeffrey Hogg.)*

granulocytes, 50% to 60% of patients with AA can be shown to have a population of PNH cells at diagnosis;[88-92] however, only 10% to 15% of patients with AA treated with immunosuppressive therapy subsequently develop clinically apparent PNH, and development of clinical disease, when it occurs, typically follows diagnosis of AA by several years.[93] In the remainder, GPI-AP– cells persist subclinically or disappear,[90] suggesting that mutant *PIGA* (and the consequent deficiency of GPI-APs) is necessary for clonal selection but is insufficient to account for the clonal expansion required for clinical manifestations of PNH to become apparent. One interpretation of these observations is that factors in addition to mutant *PIGA* determine the clinical phenotype of the disease by affecting the extent to which the *PIGA* mutant stem cells expand (see "A Two-Step Model of Paroxysmal Nocturnal Hemoglobinuria Pathogenesis"). Conceivably, a second genetic event that works additively or synergistically with mutant *PIGA* is required for clonal expansion.[77] That the extent of clonal expansion varies markedly among patients, however, suggests that the second event may have diverse etiologies and could involve somatic mutations, epigenetic phenomena, or stochastic processes.

The basis of the relationship between PNH and AA is speculative. Essentially, all patients with PNH have some evidence of marrow failure (e.g., thrombocytopenia, leukopenia, or both) during the course of their disease. Therefore, marrow injury may play a central role in the development of PNH by providing the conditions that favor the growth/survival of *PIGA*-mutant, GPI-AP– stem cells. Finding a population of GPI-AP– erythrocytes in patients with AA is clinically relevant because some studies suggest that these patients have a particularly high probability of responding to immunosuppressive therapy, and the onset of the response appears to be more rapid compared to patients with AA without a population of GPI-AP– erythrocytes.[89,92]

The presence of PNH cells has also been observed in patients with myelodysplastic syndrome (MDS).[90,92,94,95] Of note, the association between PNH and MDS appears to be confined to low-risk categories of MDS, particularly the refractory anemia (RA) variant and to a lesser extent refractory cytopenias with multilineage dysplasia (RCMD). Using high-sensitivity flow cytometry in which at least 0.003% or greater GPI-AP– red blood cells (RBCs) or polymorphonuclear leukocytes (PMNs) was classified as abnormal, Wang and colleagues reported that 21 of 119 (18%) patients with RA MDS had a population of PNH cells, whereas GPI-AP– cells were not detected in patients with RA with sideroblasts (RARS), RA with excess of blasts (RAEB), or RAEB in transformation.[92] Compared to patients with RA without a population of PNH cells (RA-PNH$^-$), patients with RA with a population of PNH cells (RA-PNH$^+$) had a distinct clinical profile characterized by the following features: (1) less-pronounced morphologic abnormalities of blood cells; (2) more severe thrombocytopenia; (3) lower rates of karyotypic abnormalities; (4) higher incidence of HLA-DR15; (5) lower rate of progression to acute leukemia; and (6) higher probability of response to cyclosporine therapy.

That a population of PNH cells is associated only with low-risk MDS variants in Japanese patients was confirmed in a North American study of 137 patients classified by World Health Organization criteria.[94] The study found a population of PNH cells in 1 of 5 (20%) patients with 5q– syndrome, in 6 of 17 (35%) patients with RA, and in 2 of 37 (5%) patients with RCMD, whereas no patient with RARS (0 of 9), RCMD-ringed sideroblasts (0 of 6), RAEB (0 of 26), MDS unspecified (0 of 10), myelodysplastic/myeloproliferative disease (0 of 10), primary myelofibrosis (0 of 5), chronic myelomonocytic leukemia (0 of 5), or AML (0 of 6) had a detectable population of GPI-AP– blood cells.

When combined with evidence of polyclonal hematopoiesis (based on the pattern of X-chromosome inactivation in female patients), the presence of a population of PNH cells in patients with MDS predicts a relatively benign clinical course and a high probability of response to immunosuppressive therapy in patients.[88] A relatively good response to immunosuppressive therapy for patients with MDS and AA was also predicted by expression of HLA-DR15 in studies of both North American and Japanese patients.[91,96] Together, these observations provide compelling indirect evidence that AA and a subgroup of low-risk MDS are immune-mediated diseases and that the immune pathophysiologic process provides the selection pressure that favors the outgrowth of *PIGA*-mutant, GPI-AP– stem cells.

Because many patients with PNH/AA have only a small proportion of complement-sensitive cells, few of the changes usually associated with hemolytic anemia are obvious. Therefore the PNH/aplastic syndrome is probably underdiagnosed. Clinicians need to maintain a high degree of suspicion, and any evidence of hemolysis (e.g., elevated serum LDH) in a patient with AA warrants evaluation for PNH. In one series of 80 European patients with PNH, AA was the first diagnosis in 23 cases (29%);[82,83] the same was true of 26 of 85 patients (31%) from Thailand[97] and 65 of 220 French patients (30%).[84] In some instances, the diagnosis of PNH is made first, and pancytopenia develops subsequently.

Thromboembolic Complications

PNH is associated with a predisposition toward intravascular thromboses, especially within the venous circulation.[4,6,82,84,98] Intraabdominal veins are the most commonly affected (Fig. 14-6, *B*). Cerebral vein (Fig. 14-6, *C*) and superficial dermal vein thrombosis also appear to be represented disproportionately. Thrombotic disease accounts for about 50% of all deaths in patients with PNH. Fatal thromboses usually involve the portal system or the brain (see Fig. 14-6, *B* and *C*).

Recurrent abdominal pain is the dominant clinical manifestation in some patients with PNH. The cause of the pain is often obscure but may be severe enough to suggest an acute abdomen warranting emergency surgery. The possibility that a thrombosis in the portal or mesenteric veins is the cause of the pain should be considered in this setting. Both transient intestinal ischemia and intestinal infarction due to thrombosis involving the microcirculation are other possible causes.

Hepatic venous thrombosis (Budd-Chiari syndrome) is a serious, potentially fatal complication of PNH (see Fig. 14-6, *B*).[4,99,100] In various series, 15% to 30% of patients with PNH had hepatic venous thrombosis, and this complication might be even more common because affected individuals can be asymptomatic when Budd-Chiari syndrome is in its early stage.[101] The clinical manifestations include nausea, abdominal pain, variable degrees of ascites, variceal bleeding, and signs of liver failure. Often, the liver increases abruptly in size, but hepatomegaly is not always noted. Three pathophysiologic stages of hepatic venous thrombosis have been defined.[101] In the early or mildest stage, only venules or small hepatic veins are involved. Patients may be asymptomatic, and therefore the condition may go unrecognized. Mild, easily controlled ascites is detected in some patients. In the second stage, larger hepatic veins are partially occluded. Ascites is noted in most patients with such abnormalities. Some individuals develop variceal bleeding, and a few become jaundiced. The third or advanced stage is characterized by complete occlusion of large hepatic veins. Ascites is almost always present, jaundice is common, and variceal bleeding occurs in a few patients. This stage is often fatal.

An increase in the level of serum LDH, alanine aminotransferase, and aspartate aminotransferase may be an early clue to the presence of hepatic vein thrombosis. Plasma concentration of conjugated bilirubin also may increase, but other biochemical tests of liver function are of limited value. Ultrasonography is the most effective, noninvasive method for early detection of hepatic vein thrombosis with a sensitivity and specificity of 85% or more.[102,103] Computed tomographic and magnetic resonance imaging (MRI) scans are more sensitive than ultrasound. MRI is better for visualizing the whole length of the vena cava and may permit differentiation of the acute form from the subacute form of the disease.[103] Radioactive isotope scanning demonstrates patchy uptake in most of the liver, except for a normal functioning, hypertrophied caudate lobe that is spared because of its separate venous drainage. Hepatic venography is definitive, but this procedure carries more risk than noninvasive techniques. Biopsy may demonstrate congestion and liver cell loss, but the procedure is hazardous and not always informative.

Small-vessel thromboses may cause severe, refractory headaches that may presage progressive cerebrovascular involvement, most commonly superior sagittal sinus thrombosis that is fatal in more than 30% of cases (see Fig. 14-6, C)[4,104,105] Signs and symptoms of cerebral sinus thrombosis include headache, nausea and vomiting, cognitive dysfunction including alterations in consciousness, and papilledema. Hemorrhagic infarction may accompany the thrombotic event, making anticoagulation untenable. Given the potentially devastating consequence of central nervous system thrombosis, a high index of suspicion is warranted, and MRI techniques are recommended for diagnosis in symptomatic patients.

Retrospective studies suggest that the monoclonal ant-C5 antibody, eculizumab (Soliris), ameliorates the risk of thrombosis in patients with PNH.[4,6,106] For this reason, patients with PNH with cerebral venous sinus (CNS) thrombosis, Budd-Chiari syndrome, or refractory splanchnic vein thrombosis are candidates for emergency treatment with eculizumab.[4]

Renal Abnormalities

Both acute and chronic renal insufficiency occurs in patients with PNH.[107,108] Acute renal insufficiency is associated with hemoglobinuric crises and may resolve without residual damage. In one series of 19 patients with PNH, however, 12 individuals had reduced values for creatinine clearance while their underlying disease was stable. Furthermore at least three of these patients had progressive renal insufficiency. Patients with PNH may also have hematuria, proteinuria, hypertension, an inability to concentrate their urine, or some combination of these abnormalities. The kidneys usually are enlarged when examined radiographically and MRI may reveal hemosiderin deposition. The renal abnormalities likely result from repeated thrombotic episodes involving small venules.

Dysphagia and Male Impotence

When closely questioned, many patients with PNH complain of painful or difficult swallowing. The symptom is often worse in the morning and appears to be exacerbated during hemolytic episodes. Studies of peristalsis have shown that the esophageal contractions that occur in this setting have 9 to 10 times the normal force. The pathogenesis of these esophageal symptoms is speculative. Inasmuch as hemoglobin binds nitric oxide, it has been proposed that the plasma free hemoglobin that is a consequence of the chronic intravascular hemolysis characteristic of PNH acts as a sump for nitric oxide.[109] Esophageal and intestinal spasm may ensue due to consumption by plasma free hemoglobin of the smooth muscle relaxing activity of nitric oxide. This hypothesis is supported by observations that patients receiving artificial hemoglobin also experience dysphagia and odynophagia.[110]

Male impotence is common in patients with PNH and is worse during hemolytic exacerbations. As is the case with dysphagia, nitric oxide deficiency that is a consequence of the sump effect of plasma free hemoglobin may underlie the erectile dysfunction.

Infections

The apparent increased incidence of infections in patients with PNH may be attributable to leukopenia, to treatment with corticosteroids, or to functional defects in leukocytes (although compelling experimental support is lacking). Even mild infections may constitute a serious hazard because they may precipitate a hemolytic exacerbation.

Physical Examination

Findings are largely nonspecific (related to anemia, thrombocytopenia, or neutropenia). Jaundice may be observed in patients with brisk hemolysis. Moderate splenomegaly and mild to moderate hepatomegaly are sometimes observed and should raise concerns about hepatic or splenic vein thrombosis.

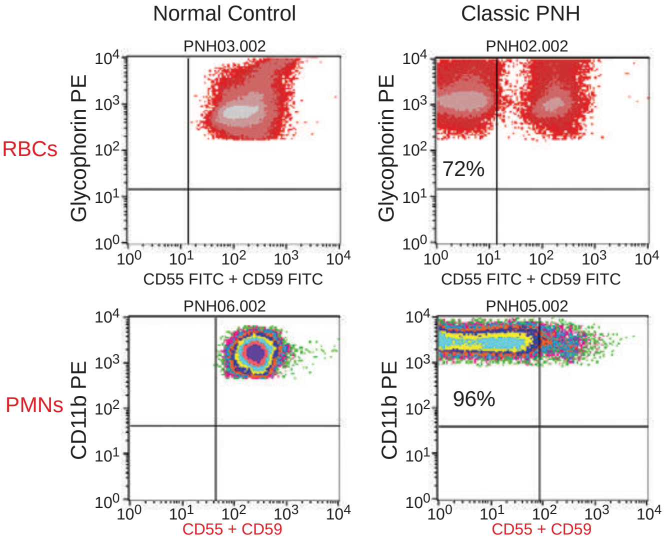

Figure 14-7 Flow cytometry diagnosis of paroxysmal nocturnal hemoglobinuria (PNH). In this example, two-color flow cytometry is used to analyze red blood cells (RBCs) *(top panels)* and neutrophils (PMNs) *(bottom panels)*. RBCs are gated on based on staining with phycoerythrin (PE)–conjugated antiglycophorin, and glycosyl phosphatidylinositol–anchored proteins (GPI-APs) are gated on using a combination of fluorescein isothiocyanate (FITC)–conjugated anti-CD55 and anti-CD59. PMNs *(bottom panels)* are gated on using PE-conjugated anti-CD11b. The top and bottom panels on the left show analysis of RBCs and PMNs from a normal volunteer (control). All the normal RBCs and PMNs express CD55 and CD59. The top and bottom panels on the right show analysis of RBCs and PMNs from a patient with classic PNH. The percentage of cells that are deficient in expression of GPI-APs is shown the inner-upper quadrant of the histograms. The percentage of deficient RBCs is almost always greater than the percentage of deficient PMNs because GPI-AP– RBCs are selectively destroyed by complement-mediated lysis, whereas GPI-AP– PMNs have a normal life span. For this reason, the size of the PNH clone is determined by the percentage of GPI-AP– PMNs rather than by the percentage of GPI-AP– RBCs.

DIAGNOSIS

Once suspected, diagnosing PNH is straightforward as deficiency of GPI-APs on peripheral blood cells is readily demonstrated by flow cytometry (Figs. 14-7 and 14-8).[111] Analysis of both RBCs and PMNs is warranted because clone size will be underestimated if only RBCs are examined because GPI-AP– red cells are selectively destroyed by complement (see Fig. 14-7). Recent transfusion will also affect the estimate of clone size if only RBCs are analyzed, but delineation of PNH phenotypes (i.e., the percentage of type I, type II, and type III cells) requires flow cytometric analysis of the erythrocyte population (see Fig. 14-4).

In addition to flow cytometric analysis, the basic initial evaluation of a patient with PNH should include complete blood count to assess the effects of the disease on production of leukocytes and platelets as well as erythrocytes; biochemical markers of hemolysis (serum concentration of LDH, bilirubin [fractionated], and haptoglobin); determination of iron stores; and bone marrow aspirate, biopsy, and cytogenetics (Box 14-3). These diagnostic studies will allow classification of patients into three

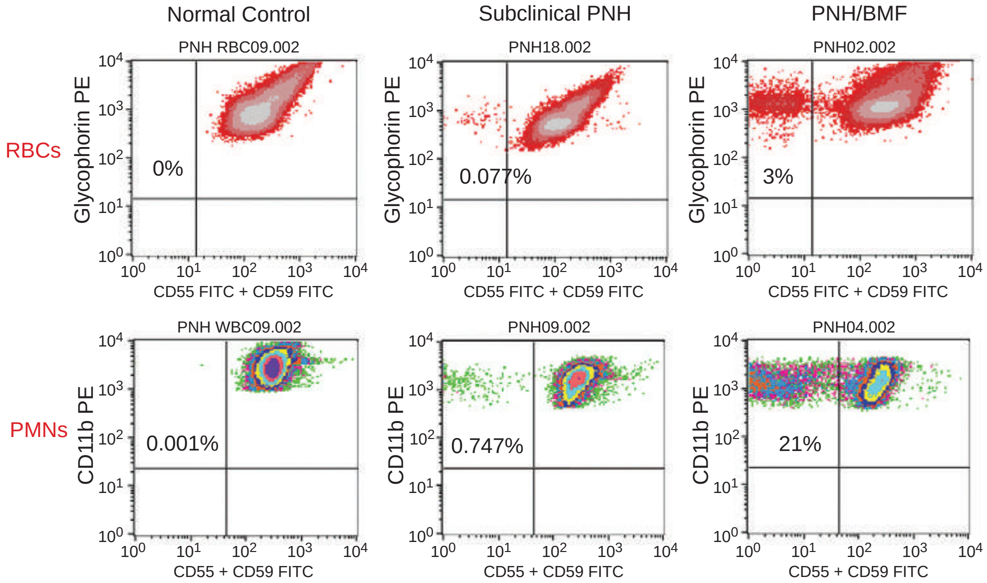

Figure 14-8 Flow cytometry of peripheral blood cells from a patient with subclinical paroxysmal nocturnal hemoglobinuria (PNH) and a patient with PNH/bone marrow failure (BMF). Please see the legend to Figure 14-6 for an explanation of the techniques used to analyze glycosyl phosphatidylinositol–anchored proteins expression on erythrocytes and neutrophils (PMNs). Patients with subclinical PNH have very small clones, typically less than 1%, and they have no biochemical evidence of hemolysis. Patients with PNH/BMF have at least biochemical evidence of hemolysis, but clone size is generally relatively small. In the case illustrated, the clone size of 21% is at the lower limit for biochemical detection of hemolysis.

groups based on the recommendation of the International PNH Interest Group (Table 14-1).[3]

In patients with classic PNH (see Fig. 14-7, Table 14-1), the leukocyte and platelet counts are usually normal or nearly normal, whereas leukopenia, thrombocytopenia, or both invariably accompany PNH in the setting of another bone marrow failure syndrome (see Fig. 14-8, Table 14-1). The reticulocyte count is needed to assess the ongoing capacity of the bone marrow to respond to the anemia. Although the reticulocyte count is elevated in patients with classic PNH, it may be inappropriately low for the degree of anemia, reflecting underlying relative insufficiency of hematopoiesis that is characteristic of the disease. Serum LDH is always markedly elevated in classic PNH. Patients with classic PNH may be iron deficient due to chronic hemoglobinuria and hemosiderinuria. Nonrandom cytogenetic abnormalities are uncommon in PNH.[77,112] The degree of serum LDH elevation is variable in patients with PNH in the setting of another bone marrow failure syndrome; however, in a large majority of patients with PNH/bone marrow failure, the clone size is less than 10%, with less than 10% of patients with PNH/bone marrow failure having a clone size of greater than 50% (see Fig. 14-8, Table 14-1).[90,113,114] Nonetheless, bone marrow aspirate and biopsy are needed to distinguish classic PNH from PNH in the setting of another bone marrow abnormality. By definition, patients with subclinical PNH (PNH-sc) have neither clinical nor biochemical evidence of hemolysis (see Fig. 14-8, Table 14-1).

Box 14-3 Basic Studies for Evaluation and Management of Paroxysmal Nocturnal Hemoglobinuria

- Complete blood count
- Reticulocyte count
- Serum concentration of lactate dehydrogenase, bilirubin (fractionated), haptoglobin
- Flow cytometric analysis of erythrocytes and granulocytes for expression of glycosyl phosphatidylinositol–anchored proteins
- Bone marrow aspirate and biopsy and cytogenetic analysis
- Serum erythropoietin concentration
- Serum concentration of blood urea nitrogen and creatinine
- Serum iron studies (iron concentration, total iron binding capacity, transferrin saturation, ferritin concentration)
- Urine hemosiderin*

*Urine hemosiderin is indicative of chronic hemolysis but provides no quantitative information.

Management Based on Classification

Completing the above diagnostic evaluation (see Box 14-3) will allow development of a systematic treatment plan (Fig. 14-9) based on disease classification (see Table 14-1).

Subclinical Paroxysmal Nocturnal Hemoglobinuria

A close association exists between PNH and AA and to a lesser extent between PNH and low-risk MDSs (see *Paroxysmal Nocturnal Hemoglobinuria and Bone Marrow Failure*). By using high-resolution flow cytometry, approximately 50% to 60% of patients with AA and 15% to 20% of patients with low-risk MDS have been found to have a detectable population of GPI-AP– erythrocytes and granulocytes.[88-90,92,94] In approximately 90% of these cases the proportion of GPI-AP– peripheral blood neutrophils is less than 25% of the total.[90]

TABLE 14-1 Classification of PNH

Category	Rate of Intravascular Hemolysis*	Bone Marrow	Flow Cytometry	Benefit from Eculizumab
Clinical PNH	Florid (markedly abnormal LDH, often with episodic macroscopic hemoglobinuria)	Cellular marrow due to erythroid hyperplasia and normal or near-normal morphology†	Large population (>50%) of GPI-AP– PMNs§	Yes
Classic				
PNH in the setting of another bone marrow failure syndrome‡	Mild (often with minimal abnormalities of biochemical markers of hemolysis)	Evidence of a concomitant bone marrow failure syndrome‡	Although variable, the percentage of GPI-AP– PMNs is usually relatively small (<50%)	Typically no, but some patients have relatively large clones and clinically significant hemolysis and may benefit from treatment
Subclinical	No clinical or biochemical evidence of intravascular hemolysis	Evidence of a concomitant bone marrow failure syndrome‡	Small (<1%) population of GPI-AP– PMNs detected by high-resolution flow cytometry	No

§Analysis of PMNs is more informative than analysis of RBCs due to selective destruction GPI-AP– RBCs.

Recent studies have investigated the natural history of PNH clones in the setting of bone marrow failure.[90,113,114] The threshold that separates PNH-sc from clinical PNH is reached when the neutrophil clone size is in the range of 20% to 25% with a corresponding GPI-AP– erythrocyte population of 3% to 5%.[113] Longitudinal studies indicate that clonal expansion occurs in 15% to 50% of cases.[90,113,114] In 10% to 25% of cases the clone disappears, and in 25% to 60% of cases the clone size persists unchanged.[90,113,114] Importantly, available evidence indicates that patients who present with subclinical PNH do not necessarily progress to clinical PNH.[90,113,114] In approximately 80% of the cases in which GPI-AP– cells are detected in the setting of bone marrow failure, the

Figure 14-9 Management of paroxysmal nocturnal hemoglobinuria (PNH). A management scheme based on classification of PNH into three categories (subclinical, PNH in the setting of another bone marrow failure syndrome [PNH/BMF], and classic PNH [see Table 14-1 for characteristics of each category]) is illustrated. *LDH,* Lactate dehydrogenase.

proportion of GPI-AP– cells is less than 1% of the total circulating granulocytes. These patients (designated PNH-sc) with very small populations of GPI-AP– cells have no clinical or biochemical evidence of hemolysis and require no specific treatment for PNH (see Fig. 14-9). Finding a population of GPI-AP– erythrocytes in patients with AA, however, may be clinically relevant because some,[89,92] but not all,[96] studies suggest that these patients have a particularly high probability of responding to immunosuppressive therapy with a more rapid rate of onset of response compared to patients with AA without a population of GPI-AP– erythrocytes.[90]

The presence of PNH cells has also been observed in patients with MDS.[90,92,94,95] As noted above (see *Paroxysmal Nocturnal Hemoglobinuria and Bone Marrow Failure*), the association between PNH and MDS appears to be confined to low-risk categories of MDS, particularly the RA variant and, to a lesser extent, the category of RCMD.[88-90,92,94]

PNH in the setting of another bone marrow failure syndrome. Patients with a bone marrow failure syndrome (AA or MDS) and a PNH clone with clinical/biochemical evidence of hemolysis are classified as PNH in the setting of another bone marrow failure syndrome (see Table 14-1). In these patients bone marrow failure dominates the clinical picture, and hemolysis is primarily an incidental finding.[90,113,114] The majority of patients with PNH/AA and PNH/MDS have relatively small PNH clones (less than 10%) and require no specific PNH therapy. In these cases treatment should focus on the underlying bone marrow failure syndrome (see Fig. 14-9). Among patients who present with clinical PNH in the setting of bone marrow failure, treatment for complications of PNH (eculizumab for hemolysis or anticoagulation for thrombosis) is required in approximately 50% of cases.[114] There is no evidence that treatment with immunosuppressive therapy influences clonal expansion either positively or negatively.

The PNH clone will be eradicated by the conditioning regimen in combination with graft-versus-host disease in patients undergoing allogeneic transplant for AA or MDS. In most instances, the size of the PNH clone is unaffected by treatment with immunosuppressive therapy, and the presence of a PNH clone should not deter immunosuppressive therapy if that approach to treatment of the underlying bone marrow failure syndrome is considered appropriate.[113,114] In instances in which, following immunosuppressive therapy, the size of the PNH clone is sufficiently large so as to produce clinical symptoms, the patient can be managed using the same approach as for patients with classic PNH.

Classic Paroxysmal Nocturnal Hemoglobinuria

Patients with classic PNH have a large clone (greater than 50%) (see Fig. 14-7), and consequently this disease subcategory is characterized by florid intravascular hemolysis as indicated by a markedly elevated serum LDH (see Table 14-1). Patients may complain of episodic hemoglobinuria, and most experience ongoing constitutional symptoms dominated by lethargy, malaise, and asthenia that can be debilitating (see Box 14-3). The complement-mediated intravascular hemolysis of PNH can be inhibited by blocking formation of the MAC (see Fig. 14-3). The MAC consists of complement components C5b, C6, C7, C8, and multiple molecules of C9. Eculizumab is a humanized monoclonal antibody that binds complement C5, preventing its activation to C5b by the APC C5 convertase and thereby inhibiting MAC formation (see Fig. 14-3).[115] In 2007, eculizumab was approved by both the U.S. Food and Drug Administration (FDA) and the European Medicines Agency for treatment of the hemolysis of PNH. Treatment of patients with classic PNH with eculizumab reduces transfusion requirements, ameliorates the anemia of PNH, and improves quality of life by resolving the debilitating constitutional symptoms associated with chronic complement-mediated intravascular hemolysis (see Fig. 14-9).[116,117,118] Following treatment, serum LDH concentration returns to normal or near normal, with approximately one half to two thirds achieving transfusion independence, but mild to moderate anemia, hyperbilirubinemia, and reticulocytosis persist in essentially all treated patients.[6,117,118]

Eculizumab appears to reduce the risk of thromboembolic complications.[106] For patients being treated with eculizumab who have no prior history of thromboembolic complications, prophylactic anticoagulation may be unnecessary, while it is recommended that anticoagulation continue for those patients who experienced a thromboembolic event prior to initiating therapy with eculizumab.[4,6]

Eculizumab is expensive (around $400,000/year in the United States), and it has no effect either on the underlying stem cell abnormality or on the associated bone marrow failure. Consequently, treatment must continue indefinitely, and leukopenia, thrombocytopenia, and reticulocytopenia, if present, persist. Treatment with eculizumab appears to have a favorable impact on survival, as a recent study of 79 patients treated between 2002 and 2010 showed the same survival as that of age- and sex-matched controls from the general population.[6,7] The contribution of eculizumab to survival cannot be quantified definitively, however, as a control patient group (PNH patients not treated with eculizumab) was not included in that study.

Reasons for Eculizumab Failure. The recommended maintenance dose of eculizumab is fixed (900 mg every 2 weeks ± 2 days) rather than being based on weight or body surface area. Some patients may show evidence of breakthrough intravascular hemolysis (i.e., a rise in LDH and development of constitutional symptoms) near the end of a treatment cycle. In these cases, breakthrough hemolysis can be ameliorated by reducing the length of the treatment cycle from 14 days to 13 days or 12 days, and in some instances, the maintenance dose of eculizumab may also need to be increased (see Fig. 14-9).

All patients with PNH have an element of bone marrow failure, and patients treated with eculizumab who have higher degrees of relative reticulocytopenia may remain anemic or even transfusion-dependent despite excellent control of intravascular hemolysis. Iron stores and serum erythropoietin concentration should be quantified in these patients, and if iron stores are adequate, and serum erythropoietin concentration is inappropriately low, a trial of recombinant erythropoietin is warranted in patients who have symptomatic anemia or who are transfusion dependent.

Following treatment with eculizumab, serum LDH returns to normal or near normal, but mild to moderate anemia and laboratory evidence of hemolysis persist in essentially all treated patients.[117,118] A subgroup of eculizumab-treated patients experience little or no improvement in either anemia or constitutional symptoms. In these patients hemolysis is mediated by opsonization of the PNH erythrocytes by activation and degradation products of complement C3, and when tested, they are found to be direct antiglobulin test–positive for C3 but not IgG.[119-121] The known pathophysiology of the PNH predicts that CD55 deficiency would result in ongoing extravascular hemolysis of PNH erythrocytes as a consequence of C3 opsonization (see Fig. 14-3) because eculizumab does not block the activity of the APC C3 convertase that is unregulated because of CD55 deficiency (see Fig. 14-3). Support for this hypothesis is provided by the studies of Risitano and colleagues,[121] who showed that in patients treated with eculizumab, a portion of the PNH erythrocytes (i.e., the CD59-deficient population) had complement C3 bound. Those studies also confirmed the direct antiglobulin test–negative designation of PNH as no C3 was found bound to PNH erythrocytes prior to initiation of treatment with eculizumab, implying that PNH erythrocytes upon which complement has been activated are destroyed directly as a consequence of MAC-mediated cytolysis. Thus those studies provide a plausible explanation for the persistent hemolytic anemia observed in PNH patients treated with eculizumab. By inhibiting formation of the MAC, eculizumab prevents direct cytolysis of PNH erythrocytes, allowing the manifestations of CD55 deficiency to become apparent in the form of aberrant regulation of the APC C3 convertase and the consequent deposition of activated C3 on the cell surface (see Fig. 14-3).[122] Covalently bound activation and degradation products of C3 then serve as opsonins that are recognized by specific receptors on reticuloendothelial cells, resulting in extravascular hemolysis.

The extravascular hemolysis of patients with PNH receiving eculizumab does not require treatment in the absence of constitutional symptoms, symptoms of anemia, or transfusion dependence. Because the process is extravascular, splenectomy or corticosteroids may ameliorate the hemolysis in symptomatic or transfusion-dependent patients by removing or inhibiting the function of phagocytic cells (see Fig. 14-9).[123] Long-term use of corticosteroids is associated with significant toxicity, however, and concerns about both postoperative and late complications temper enthusiasm for splenectomy. It is also conceivable that the primary site of phagocytosis is hepatic rather than splenic. In such cases, response to splenectomy would likely be inadequate. Based on experience in the treatment of refractory autoimmune hemolytic anemia, a trial of danazol can be considered; however, rituximab is not indicated because the process is mediated by C3 opsonization rather than opsonization by IgG antibody.

Recently, Nishimura and colleagues identified a polymorphism of C5 in 9 Japanese patients with PNH who had a poor response to treatment with eculizumab.[124] An anti-C5 antibody directed against an epitope different from that recognized by eculizumab completely blocked the hemolytic activity in the sera of the patients with the C5 polymorphism. The prevalence of the polymorphism in the Japanese population appears to be in the range of 2% to 3%.

Hematopoietic Stem Cell Transplant. Prior to the availability of eculizumab, the primary indications for transplant for PNH were bone failure; recurrent, life-threatening thrombosis; and uncontrollable hemolysis.[3,125,126] The latter process can be eliminated by treatment with eculizumab, and the thrombophilia of PNH may also respond to inhibition of intravascular hemolysis by eculizumab.[4,106] Nonetheless, transplant is the only curative therapy for PNH, and the availability of molecularly defined, matched, unrelated donors; less toxic conditioning regimens; reduction in transplant-related morbidity; and mortality and improvements in posttransplant supportive care make this option a viable alternative to medical management. The decision of who and when to transplant is complex, however, and requires an understanding of the unique pathobiology of PNH and the input of physicians experienced in transplantation and medical management of PNH.[3,125,126] The recent studies of Kelly and colleagues[6] that indicate normal survival for patients with PNH treated with eculizumab make the decision concerning medical management versus transplant even more challenging.

Other Treatment. Based on anecdotal experience, a portion of patients with classic PNH responds to danazol as first line therapy.[127,128] The basis of this response is unknown but likely involves complement inhibition because reduction in hemolysis is observed quickly (within a few days) following initiation of therapy, and PNH white blood cell clone size does not change during treatment.* Why some patients respond dramatically to danazol while others do not is unknown, but it seems plausible to suggest that responders produce a metabolite that inhibits complement, while nonresponders do not (or they produce a subtherapeutic concentration of the putative inhibitory metabolite).

Although hemolysis is ameliorated in some patients by treatment with glucocorticoids, the harm that can accrue from long-term use of prednisone cannot be overemphasized.[3] The main value of glucocorticoids may be in attenuating acute hemolytic exacerbations. Under these circumstances, brief pulses of prednisone may reduce the severity and duration of the crisis while avoiding the untoward consequences associated with long-term use.

Because the hemolysis is a consequence of a defect intrinsic to the patient's erythrocytes, the anemia of PNH responds to red cell transfusion. In addition to increasing the hemoglobin concentration, transfusion may lessen hemolysis by suppressing erythropoiesis. Concerns about inducing a hemolytic exacerbation as a consequence of infusion of small amounts of donor plasma that may contaminate red cell preparations appear unwarranted.[129]

Patients with classic PNH frequently become iron deficient as a result of renal loss (both hemoglobinuria and hemosiderinuria).[127] Clinically important iron loss from hemosiderinuria can occur even in the absence of gross hemoglobinuria. Concern for inducing a hemolytic exacerbation should not deter iron repletion because iron deficiency not only limits erythropoiesis but also exacerbates the hemolysis of PNH.[127] If a hemolytic exacerbation occurs in the setting of iron repletion, the episode can be controlled by treatment with corticosteroids or by suppression of erythropoiesis by transfusion. There is no concern about iron-replacement therapy inducing a hemolytic exacerbation in patients being treated with eculizumab because the drug inhibits hemolysis. Further, patients treated with eculizumab should not become iron deficient because treatment will resolve the hemoglobinuria and hemosiderinuria that causes the iron deficiency by blocking intravascular hemolysis.

Management of Thrombophilia. Thromboembolic complications are the leading cause of morbidity and mortality in PNH.[4] Prophylaxis against thromboembolic events in patients with PNH is an issue of active debate.[3] Current estimates of risk are based on retrospective analysis, but risk may correlate with size of the PNH clone (based on flow cytometric determination of the percentage of GPI-AP– PMNs), leading to the recommendation that patients with greater than 50% to 60% GPI-AP– PMNs be offered prophylactic anticoagulation.[4,130-132]

Although arterial thrombosis may be observed,[4,106] thromboembolic events in patients with PNH usually involve the venous system. In the absence of an absolute contraindication (e.g., hemorrhagic infarction involving the CNS), acute thrombotic events require anticoagulation with heparin. Systemic thrombolytic therapy, or thrombolytic therapy delivered via canalization directly to the affected site, can be considered in patients with acute onset of Budd-Chiari syndrome.[133-136] If there is no contraindication, anticoagulation should continue indefinitely for a patient with PNH (even if that patient is treated with eculizumab) who has experienced a thromboembolic complication. For PNH patients on long-term anticoagulation, vitamin K antagonists such as Coumadin have been used customarily. Whether low–molecular-weight heparins or novel oral anticoagulants such as direct thrombin inhibitors and factor Xa inhibitors are more, less, or equally efficacious has not been determined.

Thrombocytopenia often complicates PNH, and this issue must be addressed when formulating an anticoagulation management plan. Thrombocytopenia is a relative, but not an absolute, contraindication to anticoagulation, and transfusions should be given to maintain the platelet count in a safe range rather than withholding therapy. Patients with PNH who experience a thromboembolic event are candidates for indefinite anticoagulation, although recommendations for anticoagulation duration may be modified as more experience with the effects of eculizumab on the thrombophilia of PNH accumulates.[4]

Eculizumab appears to reduce the risk of thromboembolic complications.[4,6,106] For patients being treated with eculizumab who have no prior history of thromboembolic complications, prophylactic anticoagulation may be unnecessary, although it is recommended that anticoagulation continue for those patients who experienced a thromboembolic event prior to initiating therapy with eculizumab.[4]

Pregnancy

Women with PNH can have serious morbidity and increased mortality during pregnancy.[137,138] Because of concerns about fetal/maternal risks from exposure to potentially toxic therapy, anticoagulation and transfusion support have been the mainstay of management of patients with PNH who are pregnant. Eculizumab has been assigned to pregnancy category C (risk cannot be ruled out) by the FDA. There are no controlled studies of the use of eculizumab in human pregnancy; however, anecdotal reports and small series have identified no significant adverse effects when eculizumab is used during pregnancy, including early in gestation and, in one case, from the time of conception.[139-141] Nonetheless, until more is known about the safety of eculizumab in pregnancy, it seems prudent to restrict use of the drug to the third trimester and then only for patients who are at high risk for thrombosis and who have no acceptable therapeutic alternatives.

Moderate to severe thrombocytopenia may complicate the pregnancy, and clinically significant bleeding in this setting necessitates platelet transfusion. The incidence of clinically apparent venous thromboembolism during pregnancy in women with PNH is approximately 10%,[137] and these events are associated with a high risk of mortality.[137,138] Similar to nonpregnant patients with PNH, cerebral and hepatic veins are commonly involved sites of thrombosis. Patients who develop thrombosis should be therapeutically anticoagulated, and thrombolytic therapy and treatment with eculizumab should be considered for those with Budd-Chiari syndrome. Concurrent thrombocytopenia may necessitate platelet transfusion in patients who require anticoagulation. The role of prophylactic anticoagulation for pregnant women with PNH has not been studied systematically; however, because of the significant morbidity and mortality associated with thromboembolism in this setting, prophylaxis is recommended. Coumadin is contraindicated because of both teratogenic potential in the first trimester and hemorrhagic risks later in gestation. Anticoagulation with heparin should begin immediately once the combination of pregnancy and PNH is documented. Low–molecular-weight heparin has a hypothetical advantage over unfractionated heparin because of a lower incidence of drug-induced thrombocytopenia. Careful monitoring of the platelet count is required because thrombocytopenia may worsen during the period of anticoagulation. Anticoagulation can be discontinued briefly around the time of delivery. However, it should be restarted as soon as is feasible and continued for 6 to 12 weeks into the postpartum period because thrombosis during the puerperium is a major concern.[137] Most deliveries can be accomplished vaginally, although premature delivery may be necessary. Despite the many concerns surrounding PNH and pregnancy, successful outcomes appear to be the rule rather than the exception. Management, however, is complicated and should involve the combined efforts of an experienced hematologist and an obstetrician who specializes in dealing with high-risk pregnancies.[3]

Pediatric Paroxysmal Nocturnal Hemoglobinuria

Despite usually being considered an adult disorder, PNH can develop in children and adolescents. PNH has become a better recognized disorder over the past several years and is increasingly identified by pediatric hematologists who have become familiar with its presentation in association with bone marrow failure syndromes and its straightforward diagnosis using flow cytometry. Early studies suggested that about 10% of all patients with PNH are younger than 21 years of age at the time of diagnosis.[85,132] Current data on the incidence and prevalence of PNH in the pediatric age range are not available but might be higher due to better awareness and increased testing.

An older retrospective analysis of 26 cases underscored both similarities and differences between childhood and adult PNH.[85] In young patients the signs and symptoms of marrow failure, thrombosis, and laboratory evidence of hemolysis (e.g., elevated LDH) dominated the clinical picture. In many children PNH was initially misdiagnosed, with an average of almost 2 years from initial symptoms to the correct diagnosis. Gross hemoglobinuria as a presenting symptom appeared to be less common among children and never occurred in one third of the patients. Thrombosis occurred in approximately a third of patients, and some died of this complication. All patients had laboratory evidence of defective or ineffective hematopoiesis, either at diagnosis or over the course of their disease. The survival curve for these patients indicated that the 10-year survival rate was only 60%, although several deaths were due to complications of pancytopenia in an era before modern antibiotic and transfusion therapy.

The peculiar relationship between PNH and AA was first recognized almost a half-century ago,[142] and this association holds true for pediatric PNH. Recent case series confirm that the majority of PNH in young patients arise in the setting of bone marrow failure, usually AA. A study from the Netherlands confirmed the common presentation of marrow failure in 11 children with PNH.[143] The authors reported that 5 patients eventually underwent hematopoietic cell transplant (3 matched unrelated donors and 2 matched family donors), of whom 4 were long-term survivors. A more recent study of 12 young patients over an 18-year period documented that 10 presented with evidence of bone marrow failure and only one with hemoglobinuria.[61] Importantly, there were six children with thrombosis and five with myelodysplastic features, suggesting that the clinical presentation may be more similar to adult PNH than previously recognized.

A strong index of suspicion is needed to ensure the correct laboratory tests are ordered, which can help establish the diagnosis of PNH in children. The clinical presentation of unexplained cytopenia, particularly beyond a single lineage, or the new onset of thrombosis in an unusual location, should prompt the consideration of PNH. Flow cytometry assays for PNH are now becoming a standard part of the laboratory evaluation.[144] Most testing will include fluorescent aerolysin to identify the absence of all GPI-linked surface proteins on the surface of neutrophils and monocytes,[75] along with CD59 monoclonal antibodies to identify GPI-AP− cells among the erythrocytes.

All children with documented AA or other forms of bone marrow failure syndromes should have laboratory evaluation for PNH. However, similar to the situation for adults, the presence of small PNH clones has been documented in this setting,[145,146] but the significance of PNH-sc remains to be defined. Unless there is clinical evidence of hemolysis or a sizable clone that portends an increased risk of thrombosis, periodic monitoring of the PNH clone should be sufficient. Currently there is no predictive value to having PNH clones detected in the setting of AA, although their percentages may increase following immunosuppressive therapy.

Based on data that suggested poor long-term survival for childhood PNH, hematopoietic cell transplantation has been the recommended treatment and only available curative therapy. Matched sibling donors offer the best results, and myeloablative conditioning regimens will eradicate the PNH clones. Matched unrelated donors remain a high-risk experimental therapy, although cures have been reported.[86] Over the past 5 years, however, the availability of eculizumab is modifying the therapeutic approach to young patients with PNH. Although eculizumab is not yet formally approved for PNH patients younger than age 18 years, it has been used anecdotally with good results in the pediatric/adolescent population.[61] A recent prospective study of seven adolescents with PNH documented the safety and efficacy of short-term eculizumab treatment.[147] These data suggest that eculizumab will emerge as a therapeutic option for pediatric PNH, although further experience will be necessary to determine whether its long-term effects (and cost) make it a realistic alternative to matched transplantation. The availability of eculizumab for pediatric PNH may be particularly advantageous as a bridge prior to implementation of more definitive therapy.

COURSE AND PROGNOSIS

The clinical course of PNH is enormously variable. In rare instances, the patient may succumb to this disease within a few months of the first onset of symptoms; however, most patients experience a stable, chronic course. Rarely, the abnormal clone disappears altogether. Transformation to acute leukemia is uncommon (in the range of 1%). In some instances, but not in others, leukemic blasts are GPI-AP−.[148]

As with many other diseases, initial reports on PNH tended to emphasize the more severely affected patients, so the prognosis was generally deemed to be grave. As physicians developed a higher index of suspicion for diagnosing PNH and as diagnostic studies became more sensitive and specific, milder cases were diagnosed, and these tended to have the better long-term outlook. Nonetheless, even today, the disease must be considered a serious one in which some patients eventually succumb to its complications. The most commonly lethal of the complications of PNH are thrombotic events such as Budd-Chiari syndrome and cerebral sinus vein thromboses,[4] but complications of pancytopenia may also lead to death,[82] and in a few patients the terminal episode has been the development of acute leukemia.[148]

Course and Prognosis in the Pre-Eculizumab Era

In a study of 220 patients with PNH, from the pre-eculizumab era, followed for up to 46 years, the Kaplan-Meier survival estimate was 65% at 10 years and 48% at 15 years after diagnosis.[84] Eight-year cumulative incidence rates of the main complications of pancytopenia, thrombosis, and MDS were 15%, 28%, and 5%, respectively. Poor survival was associated with age older than 55 years at the time of diagnosis, the occurrence of thrombosis as a complication, evolution to pancytopenia, an MDS or acute leukemia, and thrombocytopenia at diagnosis. The prognosis of patients in whom AA antedated PNH was better than in those in whom it did not. In another pre-eculizumab era study of 80 consecutive patients, the median survival after diagnosis was 10 years, with 28% of patients surviving for 25 years.[82]

Course and Prognosis in the Eculizumab Era

In addition to symptomatic benefit, treatment with eculizumab appears to influence the natural history of PNH. In a retrospective study, Kelly and colleagues reported on the clinical history of 79 patients with classic PNH or PNH/BMF treated with eculizumab.[6] The median age at diagnosis was 37 years (range, 12 to 79 years) with the median age at the time of initiation of treatment with eculizumab being 46 years (range 14 to 84 years). The mean duration of treatment with eculizumab was 39 months (range, 1 to 98 months). Based on flow cytometric analysis of peripheral blood neutrophils, the average clone size among the treated patients was 96.4% (range 41.8% to 100%). Twenty-four patients (30%) had a history of a bone marrow failure syndrome at the time of diagnosis (23 with AA and 1 with MDS). Eleven patients had a history of long-term cyclosporine treatment prior to initiating therapy with eculizumab, and three patients developed aplasia requiring immunosuppressive therapy subsequent to starting treatment with eculizumab. Thrombotic episodes were reported in 27% of patients prior to starting eculizumab (including 12 cases of Budd-Chiari syndrome, 4 cases of mesenteric vein thrombosis, and 3 cases of cerebral vein thrombosis).

The investigators found that treatment with eculizumab reduced the mean yearly transfusion requirement from 19.3 units to 5.0 units. Of 61 patients who had been on eculizumab for more than 1 year, 40 (66%) became transfusion independent. Thrombosis was observed in two patients while on eculizumab (a retinal vein thrombosis in a patient also on warfarin and thrombosis of an arteriovenous fistula in a patient on hemodialysis). No thrombotic events were reported in 21 patients who discontinued prophylactic anticoagulation after starting treatment with eculizumab.

Survival of the 79 patients treated with eculizumab was the same as that of a group of age- and sex-matched controls from the general population. Three eculizumab-treated patients died. None of the deaths were deemed by the investigators to be treatment related or to be a consequence of complications of PNH. Two patients, ages 71 and 75 years, developed MDS 56 and 76 months, respectively, after starting treatment with eculizumab. One patient, age 50 years, developed AML 27 years after the initial diagnosis of PNH.

Because patients with congenital deficiency of complement C5 are at risk for meningococcal infections, all patients treated with eculizumab must be vaccinated prior to initiation of therapy.[115] However, the currently available vaccine does not protect against infection with serogroup B organisms. Two eculizumab patients developed documented meningococcal infection with *Neisseria meningitidis* serogroup B, and thereafter, a program of antibiotic prophylaxis was instituted by the investigators. There was no evidence that eculizumab affected the bone marrow failure component of the disease, as a change in platelet count was not observed in 12 patients who were thrombocytopenic prior to initiation of treatment (platelet count less than 100 × 109/L). The mean platelet count for this group was 67 × 109/L at the initiation of therapy compared to 66 × 109/L after 12 months of treatment with eculizumab, respectively.

A multicenter study involving 195 patients followed for 66 months[7] largely confirmed the findings of Kelly and colleagues.[6]

Together with the data from the natural history studies from the pre-eculizumab era, these results suggest that treatment with eculizumab alters the natural history of PNH both by reducing or eliminating transfusion requirements through inhibition of intravascular hemolysis and by virtually eradicating thromboembolic complications.[6,7] Eculizumab treatment may also reduce disease-related mortality, although the extent to which the drug enhances survival cannot be accurately determined from the studies of Kelly and colleagues[6] because the experimental design did not include a randomized control group of patients. Eculizumab does not appear to affect either the bone marrow failure component of the disease or the clonal hematopoiesis that underlies disease pathophysiology. Although PNH is a clonal disease, it is not a malignant disease, and it is this unique characteristic of PNH that allows for successful long-term symptomatic management in the absence of a treatment strategy aimed at eradicating the *PIGA*-mutant hematopoietic stem cells.[149]

CONCLUSIONS AND FUTURE DIRECTIONS

Systematic investigation of the molecular basis of PNH has provided a framework for management based on an understanding of disease pathophysiology and has led to development of targeted therapy that has improved the lives of patients and changed the natural history of the disease. Nonetheless continued investigation of new approaches to therapy aimed at obviating the extravascular hemolysis that limits eculizumab efficacy in some patients is warranted.[122,150] A better understanding of the pathobiology that underlies the thrombophilia of PNH is needed,[4,98] and defining the complex relationship between PNH and bone marrow failure syndromes that determine clonal selection and clonal expansion[77,78] may lead ultimately to therapy that targets the disease at the level of the hematopoietic stem cell. In particular, an understanding of the molecular basis of clonal expansion will be facilitated by the availability of next-generation sequencing that will allow comparison between the genomes of GPI-AP–positive and GPI-AP–negative cells from individual patients with PNH.

An important technical paper that provides guidelines for flow cytometric diagnosis of PNH.

117. Hillmen P, Hall C, Marsh JC, et al: Effect of eculizumab on hemolysis and transfusion requirements in patients with paroxysmal nocturnal hemoglobinuria. *N Engl J Med* 350:552–559, 2004.

The pivotal paper demonstrating that eculizumab effectively inhibits intravascular hemolysis in patients with PNH.

121. Risitano AM, Notaro R, Marando L, et al: Complement fraction 3 binding on erythrocytes as additional mechanism of disease in paroxysmal nocturnal hemoglobinuria patients treated by eculizumab. *Blood* 113:4094–4100, 2009.

Demonstration that treatment with eculizumab results in C3 opsonization and extravascular hemolysis of PNH erythrocytes.

142. Lewis SM, Dacie JV: The aplastic anaemia–paroxysmal nocturnal haemoglobinuria syndrome. *Br J Haematol* 13:236–251, 1967.

In this important paper, the relationship between PNH and AA is characterized.

The erythrocyte membrane is the most thoroughly studied biologic membrane. It is a small structure, less than 0.1% of the cell’s thickness and only about 1% of its weight, but its easy accessibility has enabled researchers to characterize both its primary structure and a number of its important functions. It was the original example of the fluid mosaic membrane model, a breakthrough concept proposed by Singer and Nicolson, more than 40 years ago.[1] In this model the erythrocyte membrane is composed of mobile, asymmetrically distributed proteins and lipids that interact in a variety of ways. The model has been revised in the intervening four decades, because many membrane proteins are not freely mobile but are instead diffuse in complicated patterns or are confined to discrete domains.[2,3] In this chapter I will discuss normal membrane structure, emphasizing aspects that are most involved in the genesis of membrane disease. Diseases of the red cell membrane are covered in Chapter 16.

MEMBRANE LIPIDS

Lipid Composition

Lipids compose about 50% of the weight of the red cell membrane (Table 15-1)[4-7,8,9-12] or about 1.6% of the weight of the hemoglobin. Phospholipids and unesterified (free) cholesterol predominate and are present in nearly

equal proportions (cholesterol/phospholipid molar ratio = 0.80).[4,13,14] Small amounts of glycolipids, principally globoside (73% of the glycosphingolipids) (Fig. 15-1) are also present.[11] The average red cell contains about 250 million phospholipid molecules, 195 million cholesterol molecules, 10 million glycolipid molecules, and 6 million protein molecules in a membrane whose total surface area[15] is about 140 μm^2.

Phospholipids

Phosphatidylcholine (PC), phosphatidylethanolamine (PE), sphingomyelin (SM), and phosphatidylserine (PS) are the predominant phospholipids (see Table 15-1). Their structures are shown in Figure 15-1. Small amounts of phosphatidic acid (PA), phosphatidylinositol (PI), and lysophosphatidylcholine (Lyso-PC) are also present.

At physiologic pH, PS, PA, and PI have a net negative charge, whereas the other phospholipids are electrically neutral. The polar head groups of PC and SM tend to lie parallel to the membrane surface (Fig. 15-2). The head groups of PE and PS are smaller and more cone shaped, which may help them fit in the inner bilayer.

With the exception of SM and Lyso-PC, the phospholipids have two fatty acids attached to a glycerol backbone. These are usually of similar length and attached through an ester linkage, although sometimes, particularly in PE, one of the fatty acids is a vinyl ether (plasmalogen).[10] Typically, the fatty acid attached to glycerol farthest from the polar head group (*sn*-1 position) is saturated and the nearer (*sn*-2 position) one is unsaturated.[16] PE and PS are more unsaturated than PC. In contrast, both acyl side chains are usually saturated in the SMs and the amide-linked chain (see Fig. 15-1) is often very long and interdigitates with the hydrocarbon chains of the opposite side of the bilayer. The SM amide linkage also makes its interface region more polar. The lysophospholipids have only one fatty acid and are named for the hemolysis induced because of their detergent-like properties.

Modern lipid analysis reveals hundreds of phospholipid molecular species in the red cell membrane. The majority of these are in a planar bilayer with their polar head groups exposed at each surface and their hydrophobic fatty acyl side chains buried in the bilayer core. The phospholipid head groups are probably organized in regular patterned arrays.[17] The interactions that determine these patterns probably also influence the proportion of different phospholipids in the membrane.[17]

Glycolipids and Cholesterol

Glycolipids and cholesterol are intercalated between the phospholipids in the bilayer with their long axes perpendicular to the bilayer plane (see Fig. 15-2). Red cell glycolipids are located entirely in the external half of the bilayer with their carbohydrate moieties extending into the aqueous phase. They carry many important red cell antigens, including A, B, H, Le^a, Le^b, and P.

Cholesterol is present on both sides of the bilayer[4,18] and is nearly saturated in the red cell membrane, that is, its concentration is just below the concentration where major changes in its organization occur.[19] Its distribution

Note that phosphatidylcholine and sphingomyelin share the same polar moiety (choline) and that sphingomyelin and globotetraosylceramide share the same nonpolar moiety (ceramide).

is not known, but it is probably slightly more prevalent in the outer half,[20,21] owing to its high affinity for sphingomyelin, which is concentrated in the outer bilayer. Cholesterol can flip from one side of the bilayer to the other in a fraction of a second.[22] This facilitates membrane bending, because the movement of cholesterol can offset the difference in surface pressure caused by bending and compressing one of the bilayers relative to the other. Cholesterol depletion promotes inward curvature of the membrane, whereas cholesterol enrichment favors outward deflection.[19]

Cholesterol molecules are relatively buried, because the 3-OH group, the part of the molecule that is at the aqueous interface, lies approximately at the level of the

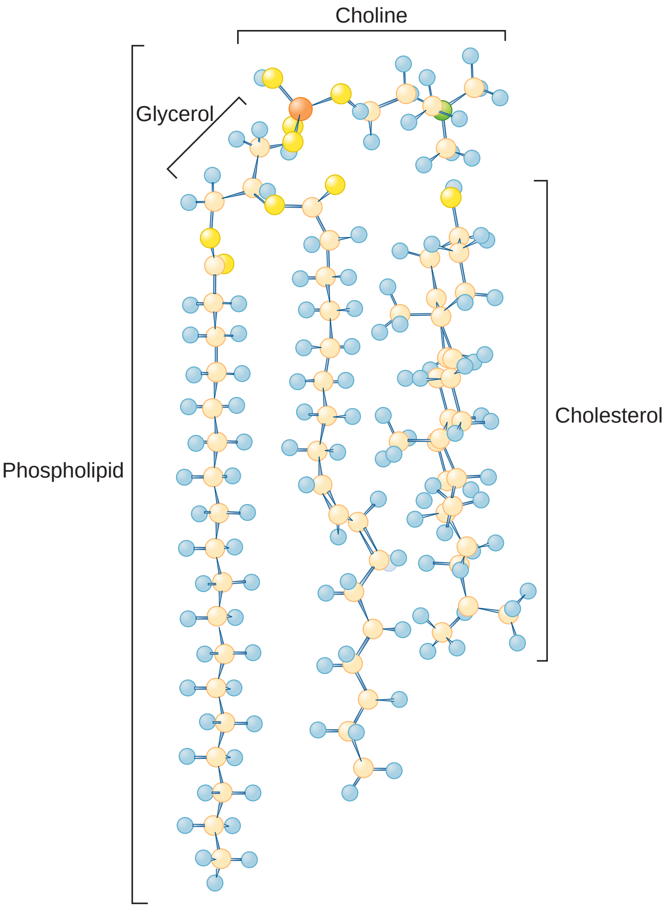

Figure 15-2 Approximate orientation of cholesterol and phospholipid molecules to each other in the membrane bilayer. Here the phospholipid is phosphatidylcholine, although often it is sphingomyelin. On average the cholesterol rings are believed to associate with the first 8 to 10 carbons of the phospholipid acyl chains. Note that the fatty acyl chain attached to the sn-1 position of the glycerol on phosphatidylcholine is saturated and straight whereas the sn-2 side chain is unsaturated and kinked (*tan,* carbon; *light blue,* hydrogen; *yellow,* oxygen; *orange,* phosphorus; *green,* nitrogen).

carbonyl group of the phospholipid fatty acids[15,23] (see Fig. 15-2). Cholesterol has important functions in buffering the fluidity of phospholipid side chains and in forming "lipid rafts," as will be described.

Asymmetric Organization of Phospholipids in the Bilayer

Trans Asymmetry

Red cell membrane phospholipids, like membrane proteins (see later), are asymmetrically distributed across the bilayer plane.[24-26] Choline phospholipids (PC and SM) are concentrated in the outer half of the bilayer and amino phospholipids (PE and PS) and PI are largely confined to the inner half (see Table 15-1).

The asymmetric distribution of phospholipids reflects a steady state involving a constant exchange (flip-flop) of phospholipids between the two bilayer hemileaflets.[25] In the red cell membrane, spontaneous transmembrane diffusion is slow, lasting several hours to a day.[27] In contrast, the enzymatic translocation of phospholipids, described in the following paragraphs, is much faster (minutes). At least three distinct activities are involved in regulating red cell membrane phospholipid asymmetry. They are discussed in several relatively recent reviews.[28-31]

Flippase. The magnesium adenosine triphosphate (Mg^{2+}-ATP)-dependent aminophospholipid translocase, or "flippase," is responsible for localization of PS in the inner leaflet by rapidly translocating it from the outer to inner leaflet. The half-time for translocation is about 5 minutes at 37°C.[32] A similar activity exists in all mammalian red cells[33] and probably in all cells. The flippase contains a critical cysteine, because it is inhibited by sulfhydryl-modifying reagents.[34] It is also inhibited by the pseudosubstrates of P-type ATPases, such as vanadate, and by high concentrations of Ca^{2+}.

Unfortunately, despite almost two decades of effort, the flippase has not been definitely identified.[28] An assortment of phospholipid transporters have been characterized in cells and organelles from bacteria to humans,[35] and some of these have been identified in red cell membranes, including ATP8A1.[36-38] ATP8A1 is an Mg^{2+}-ATPase first described in bovine chromaffin granules.[39] It is a P4-type ATPase, has the size and characteristics of the red cell membrane flippase, and translocates fluorescent PS in reconstitution experiments.[38] Yeasts lacking a homologous protein, Drs2, are defective in aminophospholipid transport.[39] But, an accessory CDC50 family protein needed for proper expression of P4-type ATPases is not found in red cells. More definitive proof—such as a gene knockout—is needed to be sure ATP8A1 is the authentic red cell flippase in mature red cells.

Floppase. The Mg^{2+}-ATP–requiring phospholipid translocase, or "floppase," is responsible for movement of phospholipids from the inner to outer leaflet of the bilayer[40] and is less specific than the flippase.[41,42] The outward lipid movement by the floppase is also much slower than the inward movement of PS by the flippase. Available evidence suggests the floppase is one of the family of ABC transporters, of which the multidrug resistance transporter (ABCB1 or MDR1 or P-glycoprotein) is the best known. The best candidate is ABCC1 (MRP1).[43,44] Long-term (48-hour) inhibition of the activity in red cells leads to loss of PC and SM from the outer bilayer but no change in the distribution of PE or PS.[45] Additionally, red cells from mice lacking the gene equivalent to ABCC1 can no longer translocate short-chain fluorescent phospholipid analogues of PC, SM, and PS from the inner to the outer bilayer.[43] However, it is not yet certain that ABCC1 can transport full-length, native phospholipids, which is a required property of the physiologic floppase.

Scramblase. The Mg^{2+}-ATP–independent, Ca^{2+}-dependent phospholipid "scramblase" causes a rapid, bidirectional movement of all phospholipids in the bilayer, resulting in the collapse of phospholipid asymmetry,[46] which may occur in less than a minute under some circumstances.

The exposure of PS on the cell surface causes red cells to adhere to each other and to endothelial cells and phagocytes and triggers clotting (see later).

After several frustrated attempts, it appears the scramblase has been cloned,[47] or at least part of the scramblase.[48] A protein called anoctamin 6 or TMEM16F (transmembrane protein 16F) is mutated and absent from patients with Scott syndrome,[47,49] a very rare, autosomal recessive disorder characterized by decreased scramblase activity (see Chapter 30).[50,51] As a consequence, activated platelets fail to expose sufficient PS on their surface to assemble prothrombinase and affected individuals have a bleeding tendency.[52] Erythrocytes and other cells also lack scramblase, but without apparent consequence. However, although anoctamin 6 is responsible for Scott syndrome, it does not account for all scramblase activity. Knockout of anoctamin 6 in the mouse impairs but does not abolish scramblase activity,[48] and other experiments show that there are at least two pathways of scramblase induction. In platelets, anoctamin 6 is not required for, but enhances, the scramblase pathway induced during apoptosis but is required by the pathway induced by thrombin and the rattlesnake venom convulxin.[49] The latter pathway is the one that is defective in Scott syndrome. This may be explained by the fact that at least 5 of the 10 members of the anoctamin/TMEM16 family have lipid scramblase activity.[53] More needs to be learned about which members are expressed in different cells and how they are triggered.

Loss of Phospholipid Asymmetry

When Ca^{2+} concentrations rise due to injury, disease, or cell death, red cells lose phospholipid asymmetry owing to activation of the scramblase and inhibition of the flippase. Because normal red cells maintain intracellular Ca^{2+} concentrations of less than a micromolar, their membranes preserve an asymmetric phospholipid distribution through their entire life span.

Phospholipid Asymmetry is Lost in Sickle and Thalassemic Red Cells. Phospholipid flip-flop is increased and phospholipid asymmetry is lost in sickle cells,[54-56] presumably owing to decreased phospholipid translocase activity[56] and uncoupling of the lipid bilayer from the underlying skeleton in the sickle cell spicules.[57] Consequently, subpopulation of circulating sickle red cells expose PS on their surface.[58] There is large variability in the numbers of such cells among sickle cell patients (0.5% to >10%). A subpopulation of thalassemic red cells also expose PS on their surface,[59] and phospholipid asymmetry is altered in diabetic red cells[60] which, like sickle cells,[61,62] tend to adhere to endothelial cells.[60,63]

Externalized PS Triggers Clotting and Phagocytosis. Cells sequester aminophospholipids on the cytoplasmic side of the plasma membrane because the exposed lipids, particularly PS, trigger the conversion of prothrombin to thrombin and promote intravascular clotting.[64-66] Loss of phospholipid asymmetry also activates the alternate complement pathway.[67]

In addition, PS is an “eat me” signal. Macrophages bind and ingest cells, or even liposomes, that have PS exposed on their outer surfaces.[68-70] Exposure of PS is one of the earliest events in apoptosis, and the PS receptor seems to have evolved to scavenge dead or dying cells that have activated scramblase during apoptosis. Expelled erythroblast nuclei also display PS on their surface and are removed by this mechanism.[71]

A protein called PSR was initially believed to be the PS receptor,[72,73] however that proved incorrect.[74-76] Three different PS receptors have been identified that appear to be real: Tim4,[77] Bal1,[78] and stabilin-2.[79] Bal1 functions as the receptor for the ELMO/Dock/Rac pathway that directs the actin cytoskeleton to engulf apoptotic corpses.[80] Stabilin-2 interacts with the intracellular adaptor GULP to activate Rac1 and coordinates with Bal1.[81] Tim4 does not appear to signal but serves primarily as a tethering receptor.[82] The interplay between these receptors and other parts of the phagocytic system is fascinating but complex, and its discussion is beyond the scope of this chapter.

Cis Asymmetry

Protein-Bound Lipids. There is evidence that some transmembrane proteins interact with neighboring “boundary” lipids in a dynamic fashion[83] whereas others bind lipids so tightly that they resist detergent extraction.[84] Presumably the latter proteins bear high-affinity lipid-binding sites. In either case, but particularly when lipids are tightly bound, they must slow the next layer of lipids that they interact with and so on, so that integral proteins exert a kind of “crowd control” on the lipids in the vicinity.

The structure, and in some cases the function, of integral membrane proteins is dependent on the surrounding phospholipids.[83] Membrane proteins can be parochial in their choice of lipid partners. For example, specific lipids are required for the enzymatic functions of the sodium and calcium pumps whereas glycophorin A (to be discussed), binds anionic (PS, PI) but not choline (PC, SM) phospholipids, and those lipids are relatively tightly bound.[85] Positively charged amino acids are concentrated on the cytoplasmic side of the bilayer-spanning domains of membrane proteins, in part because their position determines the orientation of the protein.[86,87] Although it is not well documented, anionic phospholipids probably cluster near these regions of positive charge. Surface-bound membrane proteins such as spectrin and protein 4.1R, which bind preferentially to anionic phospholipids,[88,89] may also contribute to the nonrandom topography of inner membrane phospholipids. And, conversely, the lipids appear to contribute to the stability of the membrane skeleton.[90,91]

Membrane Lipid Rafts. Lipid rafts are domains within the lipid bilayer that were initially defined by being insoluble in cold, nonionic detergents but have since been defined by multiple other techniques.[92] They are present in all cells and have been implicated in a variety of sorting and signaling processes.[92-96] They are rich in cholesterol, sphingomyelin, and glycosylphosphatidylinositol (GPI)-

anchored proteins; have more ordered acyl side chains; and are thicker than nonraft bilayer domains.[93,97] Cholesterol prefers the straighter and stiffer acyl chains of sphingomyelin to more disordered phospholipid side chains and is enriched in the rafts.[96] The extra length of glycosphingolipid side chains increases the thickness of the rafts and promotes further segregation. Various measurements indicate that lipid rafts are dynamic, nanoscale (10 to 20 nm) structures that assemble reversibly into larger structures, often for functional reasons.[92] Red cells lipid rafts are 100 to 300 nm and have an irregular shape.[98]

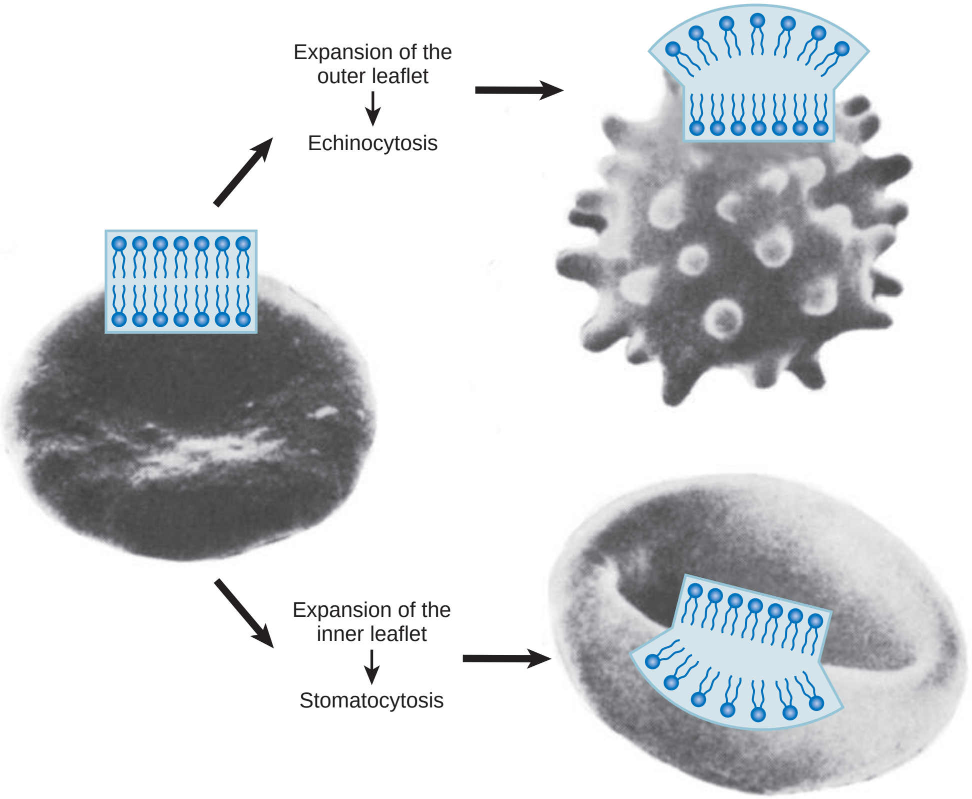
Red cell lipid rafts contain a complex mixture of membrane proteins, including stomatin, flotillin-1 and flotillin-2, the Duffy protein receptor (DARC), heterotrimeric Gα_s GPI-anchored proteins such as CD55, CD58, and CD59, and at least some band 3 molecules.[98-101] Proteins with myristate or palmitate side chains also tend to partition into the rafts,[102-104] whereas proteins with prenyl side chains are excluded.[103]

Because the glycolipid anchor of GPI-linked proteins is only embedded in the outer leaflet of the bilayer, GPI-linked proteins are much more laterally mobile than transmembrane proteins that interact with the membrane skeleton (discussed later). This high mobility may be important in recruiting complement regulatory proteins to sites of complement activation. Defective biosynthesis of the GPI anchor precludes attachment of GPI-linked proteins to the membrane, causing increased susceptibility to hemolysis by complement, as clinically manifest by paroxysmal nocturnal hemoglobinuria (see Chapter 14).[105]

Depletion of cholesterol from the red cell membrane blocks raft formation and the ability of raft-associated proteins to form membrane microdomains. It appears there are different kinds of lipid rafts in the membrane, with different protein components and different fates,[101] but this is not well defined. Although the function of the rafts in normal red cell physiology remains to be determined, they seem to be critical for the invasion of red cells by malarial parasites.[106]

Bilayer Couple Effect

The shape of the lipid bilayer is responsive to very slight variations (<0.4%)[107,108] in the surface area of its inner and outer halves. This is termed the *bilayer couple effect.*[109] It reflects the tight packing of membrane lipids, the independent motion of lipids in each half of the bilayer, and the extreme thinness of the membrane (<0.1% of the diameter of the cell). Processes that expand the outer bilayer (or contract the inner) will produce uniform membrane spiculation, called *echinocytosis* (Fig. 15-3). Conversely, relative expansion of the inner bilayer will lead to membrane invagination and cup-shaped red



Expansion of the outer leaflet

Expansion of the inner leaflet
Stomatocytosis

Figure 15-3 Bilayer couple effect. Compounds or processes that selectively expand the outer leaflet of the lipid bilayer produce uniform membrane spiculation (echinocytosis). Selective expansion of the inner leaflet of the bilayer leads to membrane invagination and cup-shaped red cells (stomatocytosis). *(Modified from Palek J, Jarolim P: Clinical expression and laboratory detection of red cell membrane protein mutations.* Semin Hematol *30:249, 1993.)*

cells (i.e., *stomatocytosis*). Strongly charged amphipathic compounds, such as phospholipids, cause echinocytosis.[108,109] They are trapped in the outer bilayer by their fixed charge. Permeable amphipaths (e.g., weak acids and bases that can cross the membrane in their uncharged form) will cause the membrane to extend toward the side of greater accumulation.[110-112] In general, cationic compounds will accumulate in the negatively charged inner bilayer and anionic compounds will partition to the neutral outer bilayer. Even subtle effects, such as differences in the cross-sectional area of lipid head groups or fatty acyl tails, can lead to changes in membrane curvature.[112]

The bilayer couple effect predicts that shape changes resulting from expansion of one lipid leaflet can be reversed by a commensurate alteration in the other. For example, the intensely spiculated red cells of patients with abetalipoproteinemia can be almost completely converted to biconcave disks by the addition of small amounts (0.1 mM) of chlorpromazine, a cationic amphipath.[113] Unfortunately, this simple test has not been applied to other pathologic red cells, so it is difficult to estimate how often bilayer couple effects dictate cell shape in vivo. But shape is not totally explained by the bilayer couple hypothesis, because protein scaffolds, insertion of proteins into the lipid bilayer, the intrinsic shape of proteins that attach to the bilayer, and crowding of proteins on the membrane surface can all cause membranes to curve.[114] The contribution of these factors to red cell shape is not well studied, but it seems likely that the spectrin-actin protein scaffold and the many integral membrane proteins must be important.

Membrane Phosphoinositides

The polar head group of this interesting class of phospholipids contains phosphatidylinositol (PI), or its phosphorylated forms, PI 4-monophosphate and PI 4,5-bisphosphate (PIP and PIP_2), respectively. In mature erythrocytes, phosphoinositides represent 2% to 5% of the total phospholipids. They reside at the inner membrane surface and undergo rapid phosphorylation and dephosphorylation.[115] In nucleated cells, phosphoinositides are precursors of important intracellular second messengers such as inositol-1,4,5-triphosphate and diacylglycerol. In red cells they help regulate Ca^{2+} transport, interact with membrane proteins such as glycophorin C, spectrin, and protein 4.1R (see later), and may influence discocyte-echinocyte shape transformation.

Lipid Mobility

Acyl Side Chains

Purified Lipids Exist in Gel or Liquid Crystalline States. Purified phospholipids exhibit discrete, liquid crystalline to gel phase transitions that are dependent on the length and degree of unsaturation of their acyl side chains. The presence of a double bond in the acyl chain increases the disorder and flexibility all along the hydrocarbon chain,[116,117] especially toward the terminal methyl end. Below the temperature of the liquid crystalline to gel transition, acyl chains of purified lipids are extended in stiff, parallel, hexagonally packed arrays that are more nearly solid than liquid.

Cholesterol Creates an Intermediate State between Gel and Liquid Lipids. Cholesterol buffers the extremes of the gel and liquid crystalline states. At temperatures above the gel-liquid phase transition, cholesterol partially immobilizes the acyl chains of phospholipids, particularly the proximal eight to ten carbons that are adjacent to the bulky steroid nucleus.[118] Below this transition, cholesterol disrupts the ordering of the acyl chains, in effect preserving membrane fluidity.[119,120] The net result is that cholesterol tends to abolish the gel to liquid crystalline transition and create a condition of intermediate fluidity in which the proximal ends of the hydrocarbon chains are extended and relatively rigid and the distal ends are disordered and fluid.

The red cell membrane contains relatively large amounts of cholesterol (cholesterol/phospholipid = 0.8 mol/mol) and is relatively less fluid than other plasma membranes.[121] The inner bilayer is somewhat more fluid than the outer,[122] probably because it contains more unsaturated fatty acids.

Lateral Diffusion

Phospholipids move about rapidly within each plane of *model* lipid bilayers.[121,123,124] From the measured lateral diffusion constants (2 to 5×10^{-8} cm^2/s), one can calculate that phospholipids exchange places with their neighbors about 10^7 times per second. This rate is somewhat damped in the red cell membrane (estimated diffusion constant of 1.4×10^{-8} cm^2/s),[125] but the difference is about what would be expected, considering the effects of cholesterol on the lateral mobility of phospholipids.[124]

Lipid Renewal Pathways

Mature Erythrocytes Cannot Synthesize Lipids. Mature erythrocytes are unable to synthesize fatty acids, phospholipids, or cholesterol de novo and depend on lipid exchange and fatty acid acylation as mechanisms for phospholipid repair and renewal (Fig. 15-4). Damaged chains are removed by phospholipase A_2, producing a lysophospholipid. Plasma-derived fatty acids are esterified to acyl-CoA by acyl-CoA synthetases, especially ACSL6,[126] and transferred to the lysophospholipids by acyl-CoA: lysophospholipid acyltransferases.[127] In theory this enzyme should facilitate the renewal of lost or damaged fatty acid side chains and should prevent the accumulation of deleterious lysophosphatides within the membrane; however, it is not certain that the phospholipases necessary to remove damaged fatty acids operate in the red cell.

This renewal pathway, although limited, permits a slow replacement of membrane lipid components. Approximately 30 days are required before erythrocyte lipids reach equilibrium after a change in dietary fatty acids.[128] Theoretically this could be pathologically significant in persons on unusual diets (e.g., infants receiving a high intake of medium-chain triglycerides); however, to date, no pathologic consequences have been reported.

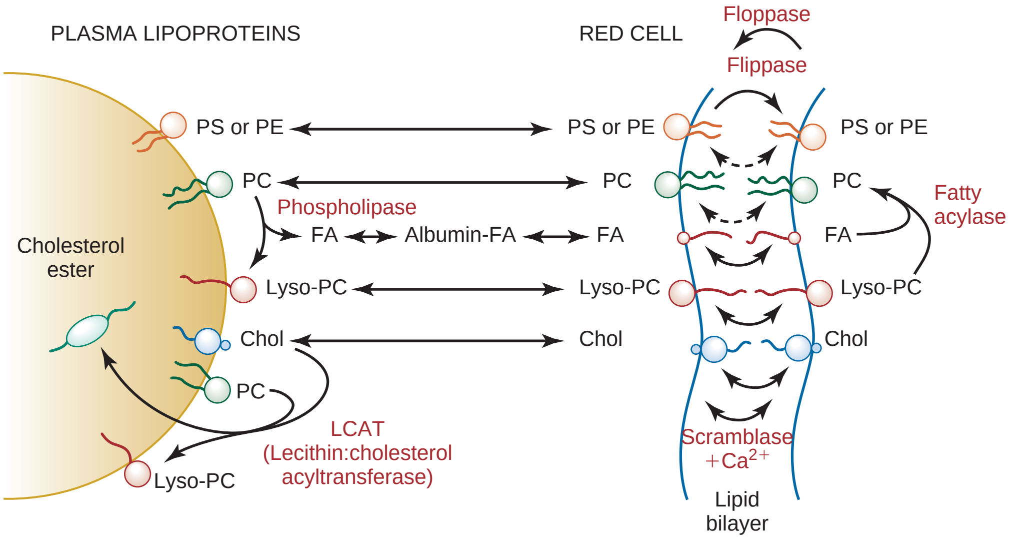

Figure 15-4 Pathways for lipid exchange and fatty acid replacement in the red cell membrane. *Chol,* Cholesterol; *FA,* fatty acid; *Lyso-PC,* lysophosphatidylcholine; *PC,* phosphatidylcholine; *PS,* phosphatidylserine; *PE,* phosphatidylethanolamine.

Esterification Depletes Red Cell Cholesterol. Red cell membrane cholesterol (unesterified) exchanges readily with the unesterified cholesterol in plasma lipoproteins ($t_{1/2}$ = 7 hr), where it is partially converted to *esterified* cholesterol by the action of lecithin:cholesterol acyltransferase (LCAT). Because the newly formed cholesteryl ester cannot return to the red cell membrane, LCAT catalyzes a unidirectional pathway (see Fig. 15-4) that depletes the membrane of cholesterol and decreases its surface area. Conversely, if LCAT is absent or inhibited, excess membrane cholesterol accumulates, expanding the membrane surface area and resulting in target cells.[129]

MEMBRANE PROTEINS

Composition

The red cell membrane (or "ghost") contains nearly 20 major proteins and more than 300 minor ones (Table 15-2).[130-145,146,147-161] Even defining what is a red cell membrane protein is difficult because plasma and cytoplasmic proteins bind to membrane constituents to varying degrees under different conditions. The major proteins of the red cell membrane (Fig. 15-5; see Table 15-2) and their disorders have been intensively studied,[162,163] and, in most cases, their genes have been cloned.

The protein constituents of the red cell membrane are usually defined by hypotonic hemolysis of red cells[164] followed by polyacrylamide gel electrophoresis (PAGE) in sodium dodecyl sulfate (SDS).[8] In general, membrane proteins are classified as either *integral* or *peripheral.* Integral membrane proteins penetrate or traverse the lipid bilayer and interact with the hydrophobic lipid core. They include band 3, the anion exchange channel, and the glycophorins, which generate a negative charge at the cell surface, and other proteins that function as channels or receptors and display surface antigens (Fig. 15-6). Integral membrane proteins form the randomly distributed 8- to 10-nm intramembranous particles seen on freeze-cleave electron microscopy of red cell membranes.[165] Peripheral proteins interact with integral proteins or lipids at the membrane surface but do not penetrate into the lipid bilayer core. In the red cell, the major peripheral membrane proteins are located on the cytoplasmic membrane face and include enzymes such as glyceraldehyde-3-phosphate dehydrogenase (G3PD) and the structural proteins of the membrane skeleton. The red cell membrane skeleton is operationally defined as the insoluble proteinaceous residue that remains after extraction of red cells[166] or their ghosts[167] with the nonionic detergent Triton X-100. The membrane skeleton contains roughly half of the membrane protein mass and includes such proteins as spectrin, actin, protein 4.1R, p55, adducin, dematin, tropomyosin, tropomodulin, ankyrin, and part of band 3 and protein 4.2 (see Fig. 15-6).

INTEGRAL MEMBRANE PROTEINS

Band 3 (SLC4A1, AE1)

Band 3 is the major integral membrane protein of the red blood cell, comprising 25% to 30% of cell membrane protein (~1.2 million copies per cell). It is also called anion exchange protein 1 (AE1), but its official appellation is solute carrier family 4 (anion exchanger), member 1 or SLC4A1. It is expressed early in erythropoiesis and peaks at the orthochromic erythroblast stage.[168] It encodes a 911-amino acid polypeptide of 102 kD.[169,170] Band 3 migrates as a diffuse band on SDS gels (see Fig. 15-5)

*Size of the mature protein chain without any signal peptide, propeptides, or cleaved initiator methionine, but not including glycosylation, phosphorylation, fatty acid acylation, and other posttranslational modifications.

[†] Copies of proteins 4.1 and 4.2 and G3PD were based on an estimate of 5.7×10^{-13} g protein/ghost[8] and on the approximate proportion of each protein, estimated from densitometry of SDS gels. Numbers of spectrins and ankyrins were measured directly by radioimmunoassay.[131] The copy number of other proteins were taken or calculated from data in the following references: AChE,[132,133] β actin,[134] α and β adducin,[135] aquaporin[136] band 3,[137] carbonic anhydrase 2,[138] Ca^{2+}-ATPase,[139] CD44,[140] CD47,[141] CD55,[122,142] CD58,[140] CD59,[143] CD99,[157] CR1,[142] dematin,[144] Duffy,[145] Gárdos channel,[146] glucose transporter 1 (Glut1),[142] glycophorins A and B,[147] glycophorins C and D,[148] Kell,[149] Lu,[133,150] LW,[151] Na^+,K^+-ATPase,[146,152] nucleoside transporter,[142] p55,[153] RhAG,[154] Rh polypeptide,[154] tropomodulin,[155] tropomyosin,[156] urea transporter,[133,158] and Xg glycoprotein.[133,142]

[‡] Glycosylphosphatidylinositol (G)-linked proteins and heavily palmitoylated (P) proteins such as p55 are classified as integral proteins.

[§] OMIM: http://www.ncbi.nlm.nih.gov/omim.

[‖] NCBI Protein database: http://www.ncbi.nlm.nih.gov/protein.

[¶] Data shown are for full-length ankyrin (band 2.1), the major isoform, except for the number of copies/cell, which includes the smaller isoforms: band 2.2 = 195 kD, band 2.3 = 175 kD, and band 2.6 = 145 kD.

[**] Glycophorin E mRNA has been identified, but it is not certain that the mRNA is translated.

[††] The full-length form of protein 4.2 is 721 amino acids (isoform 1, 79,797 daltons). Features of the protein, such as the band 3–binding site or the palmitoylation site, are numbered using this sequence. However, the common isoform is only 691 amino acids long (isoform 2, 76,878 daltons, NP_001107606.1). It lacks amino acids G4 to D33.

[‡‡] The number of tropomyosins includes the contribution of both the *TPM1* and *TPM3* genes. Tropomyosin has many isoforms.[159] Red cell tropomyosin is composed of the hTm5b isoform of *TPM1* (also called TM5b) and the hTM5 isoform of *TPM3* (also called Tm5NM1).[160] The larger band on SDS gels of red cell membranes is the hTM5 isoform. The author was unable to link the sequence of the hTM5b isoform to any of the reference sequences in the NCBI Protein Database. The sequence listed is the generic 284-amino acid sequence.

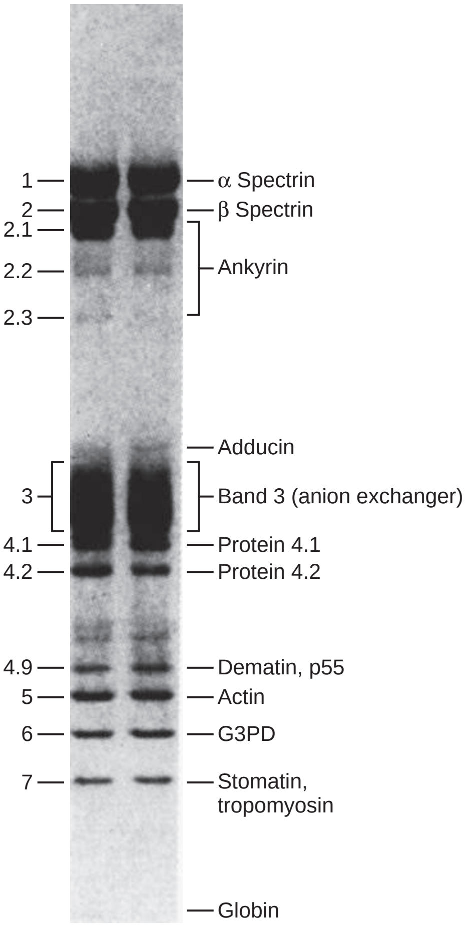

Figure 15-5 Major proteins of the red blood cell membrane separated by SDS gel electrophoresis. The glycophorins and Rh proteins do not bind the Coomassie Blue stain and are not visible. *G3PD,* Glyceraldehyde-3-phosphate dehydrogenase. *(Modified from Costa FF, Agre P, Watkins PC, et al: Linkage of dominant hereditary spherocytosis to the gene for the erythrocyte membrane-skeleton protein ankyrin.* N Engl J Med *323:1046, 1990.)*

owing to heterogeneous *N*-glycosylation.[171] It is divided into a cytoplasmic domain that is a key attachment site for the membrane skeleton, glycolytic enzymes, and hemoglobin and a membrane domain anion exchange channel that aids carbon dioxide (CO_2) transport.

Cytoplasmic Protein Binding Domain

The 43-kD amino-terminal (N-terminal) domain of band 3 (amino acids 1 to 359) resides in the cytoplasm and is released when red cell membranes are treated with chymotrypsin or trypsin.[172] The first 45 amino acids are highly acidic and stretch into the cytoplasm (Fig. 15-7).[173-176] The remainder of the domain is folded but flexible, expanding at high pH and contracting at low pH.[177]

The N-Terminal Sequence Binds Glycolytic Enzymes, Peroxiredoxin-2, and Deoxyhemoglobin and is an Oxygen-Regulated Membrane Metabolon. The first 23 amino acids of band 3 contain two tandem repeats terminating in the sequences DDY_8ED and $EEY_{21}ED$. G3PD,[178] phosphofructokinase (PFK),[179] aldolase[180,181] and deoxyhemoglobin[182] all bind in this region. So does peroxiredoxin-2.[183] Aldolase requires both sites to bind, G3PD binds separately to each, and PFK and deoxyhemoglobin bind to the more distal site.[182,184] In confirmation, the red cells from a child with a mutant band 3 that lacks the first 11 amino acids (Bd3 Neapolis) contain no membrane bound aldolase.[185]

The glycolytic enzyme complex also binds to a site near the junction of the cytoplasmic and membrane domains of band 3 (amino acids 356 to 384), which lies close to the N-terminus in the folded protein.[186] Enzymes in the glycolytic complex can be crosslinked to proteins in both the ankyrin complex and the actin junctional complex,[186] which suggests the glycolytic enzymes attach to band 3 dimers in both complexes (see Fig. 15-6).

There are more than enough band 3 molecules to bind all the peroxiredoxin-2 (~200,000 copies), G3PD (~500,000 copies), aldolase (~20,000 copies), and PFK (~6,000 copies). About 65% of G3PD, 40% of aldolase, and 50% of PFK are membrane bound in the intact red cell.[178,179] PGK may also attach to band 3,[187] but the numbers of bound molecules are small (~230 copies).

Deoxyhemoglobin binding is well documented.[182,188] Its affinity is weak ($kD_{(deoxy\ Hb)} = 0.3$ mM), but because the concentration of hemoglobin is so high in red cells, roughly half of the band 3 molecules are bound to deoxyhemoglobin under physiologic conditions.[188,189] Hemichromes, a partially denatured form of hemoglobin, bind more avidly than hemoglobin and cause band 3 to cluster,[189-191] which is believed to target the cell for phagocytosis (see later section, "Membrane Changes Associated with Aging and Senescence of Red Cells").

G3PD, PFK, and aldolase are inhibited when attached to the membrane.[180,181,192,193] In addition, lactic dehydrogenase (LDH) and pyruvate kinase (PK) also localize to the membrane, even though they *do not* bind to band 3.[193] All five enzymes are displaced into the cytoplasm by an antibody to the N-terminus of band 3, by deoxyhemoglobin, or by $p72^{syk}$ phosphorylation of tyrosines 8 and 21, which lie in the middle of the two binding sites.[193,194] Similarly in mice, even though the acidic N-terminal domain of band 3 is not well conserved, glycolytic enzymes bind to the red cell membrane in a band 3–dependent manner and redistribute to the cytoplasm when hemoglobin is deoxygenated and bound to band 3 or band 3 is deleted.[195,196]

The data suggest that many of the enzymes in the glycolytic pathway form a complex—or more accurately a series of complexes because the wide variation in numbers of enzyme molecules means they cannot form a single stoichiometric complex. The complexes (or "metabolons") are bound to band 3, and their interaction can be regulated by tyrosine phosphorylation and the state of hemoglobin oxygenation,[193,194,197,198] and perhaps by substrates and cofactors of the enzymes (Fig. 15-8).[178,180,187] The enzymes are in discrete clumps along the membrane, which also supports the idea of a metabolon (see Fig. 15-8, *A*). In addition, when metabolic fluxes are measured in *intact* normal red cells, activating glycolysis by displacing the glycolytic enzymes from band 3 increases

Figure 15-6 Schematic model of the red cell membrane. Most of the known protein contacts are shown, but the relative positions of the proteins to each other within the various complexes are mostly not known. The major proteins are drawn roughly to scale, but the shapes are mostly imaginary. For clarity, less than the expected six spectrin/protein 4.1 complexes and their attached proteins are shown. Roughly 40% of the band 3 molecules are tetramers in a complex with ankyrin and other integral proteins near the spectrin self-association site (ankyrin complex). A fraction of the band 3 dimers are located near the spectrin/actin junction and bind to spectrin via protein 4.1, protein 4.2, and adducin (actin junctional complex). It is likely these two complexes, with their associated proteins, are large enough that they sometimes contact each other. The remaining band 3 dimers float untethered within the lipid bilayer (unbound band 3). To show its various interactions, the actin protofilament is drawn perpendicular to the plane of the lipid bilayer, jutting into the cytoplasm. However, it actually lies parallel to the membrane. The complexes of proteins associated with band 3 are not constant—some proteins are present in much smaller numbers than others (e.g., Rh, Kell, Kx, Duffy, LW, phosphofructokinase, and aldolase). The amounts of p55, adducin, and dematin are also insufficient to interact with all the spectrin/protein 4.1/actin complexes. As a consequence, the ankyrin and actin junctional complexes must vary in composition. Dematin is shown here as a trimer, though recent evidence suggests it is probably monomeric. For visual clarity, peroxiredoxin-2 is shown attached just to unbound band 3 but there is no evidence for this selectivity. *CH1* and *CH2,* Actin-binding domains of β spectrin; *EF,* Ca^{2+}-binding EF hand domain of α spectrin; *GEC,* glycolytic enzyme complex (G3PD, phosphofructokinase, and aldolase); *GPA,* glycophorin A; *GPB,* glycophorin B; *GPC,* glycophorin C; *Prx2,* peroxiredoxin-2; *RhAG,* Rh-associated glycoprotein. *(Modified from Korsgren C, Peters LL, Lux SE: Protein 4.2 binds to the carboxyl-terminal EF-hands of erythroid alpha-spectrin in a calcium- and calmodulin-dependent manner.* J Biol Chem *285:4757–4770, 2010.)*

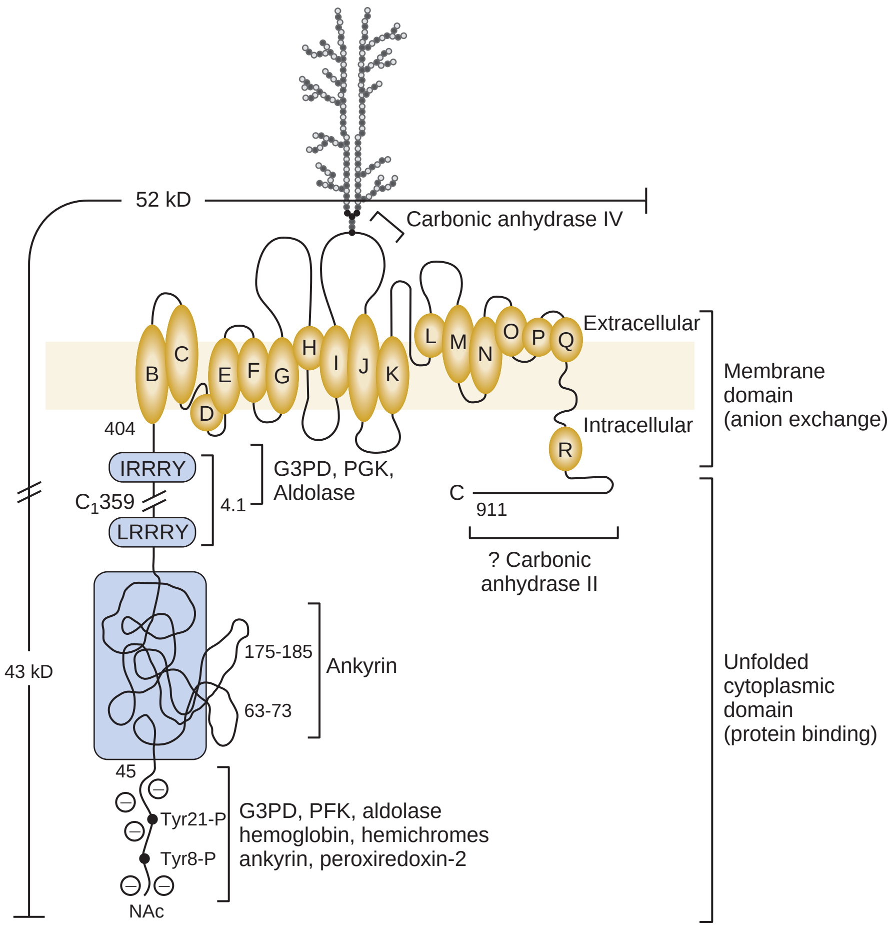

Figure 15-7 Organizational model of human erythrocyte band 3 (anion exchange protein, AE1). The protein is divided into two structurally and functionally distinct domains: an approximately 43-kD cytoplasmic domain (amino acids 1 to 359) that contains binding sites for several cellular proteins and an approximately 52-kD transmembrane domain (amino acids 360 to 911) that forms the anion exchange channel. The two regions can be separated by chymotrypsin cleavage at the inner membrane *(C_1)*. *Cytoplasmic domain:* The highly acidic N-terminus (amino acids 1 to 45) binds deoxyhemoglobin, hemichromes, and the glycolytic enzymes phosphoglycerate kinase *(PGK)*, aldolase, and glyceraldehyde-3-phosphate dehydrogenase *(G3PD)*. Enzyme attachment is blocked by phosphorylation of tyrosines 8 and 21. Antibodies to the N-terminus also interfere with ankyrin binding, but the main ankyrin sites are amino acids 63 to 73 and 175 to 185. Protein 4.1 binds to two sites with the (I/L)RRRY motif, near the end of the domain. The binding site for protein 4.2 has not been clearly identified. *Membrane domain:* The best current model[173] is based on homology with the structure of the ClC bacterial chloride channel.[174-176] The intramembrane helices are lettered as they are in the ClC channel. A complex carbohydrate structure is attached to Asn642. Carbonic anhydrase IV (CA-IV) binds to the extracellular loop of band 3 between helices I and J, and there is evidence, although disputed, that CA-II binds to the C-terminal segment. Both are perfectly positioned to shuttle HCO_3^- ions to or from the plasma through band 3.

glycolytic fluxes by 45% and decreases utilization of the pentose phosphate pathway by 66%.[198]

The obvious reason for a complex of glycolytic enzymes would be to increase the efficiency of glycolysis by channeling glycolytic intermediates from one enzyme to the next (see Fig. 15-8, C). The complex is conveniently located near band 3, which transports the phosphate needed to make ATP. Band 3 also transports phosphoenolpyruvate, pyruvate, and lactate, all substrates or products of the putative complex. The immediate modification of substrates on the inner membrane surface also prevents back-flux through transport channels, increasing the efficiency of transport.

There is strong evidence that human red cell membranes compartmentalize ATP (see Fig. 15-8, *B*).[199,200] The membrane ATP pool is in contact with β spectrin, ankyrin, band 3, and G3PD,[200] and it fuels the Ca^{2+}-ATPase and Na^+,K^+-ATPase pumps[201] and presumably the phospholipid flippase.

Interestingly, the existence of a membrane bound complex of glycolytic enzymes was postulated more than 45 years ago[202] and was indirectly observed more than 35 years ago,[203,204] but the interpretation was not generally accepted. The membrane ATP pool is another discredited old idea[205,206] that has been revived.

The Cytoplasmic Domain Is Where the Membrane Skeleton Attaches. *Ankyrin* links the major membrane skeletal protein spectrin to the plasma membrane of the red cell by binding to a pair of adjacent beta hairpin loops in the cytoplasmic domain of band 3 formed by amino acids 63-73 and 175-185 (Fig. 15-9; see also Fig. 15-7).[207-209] There is considerable evidence that ankyrin also interacts with the acidic N-terminal domain of

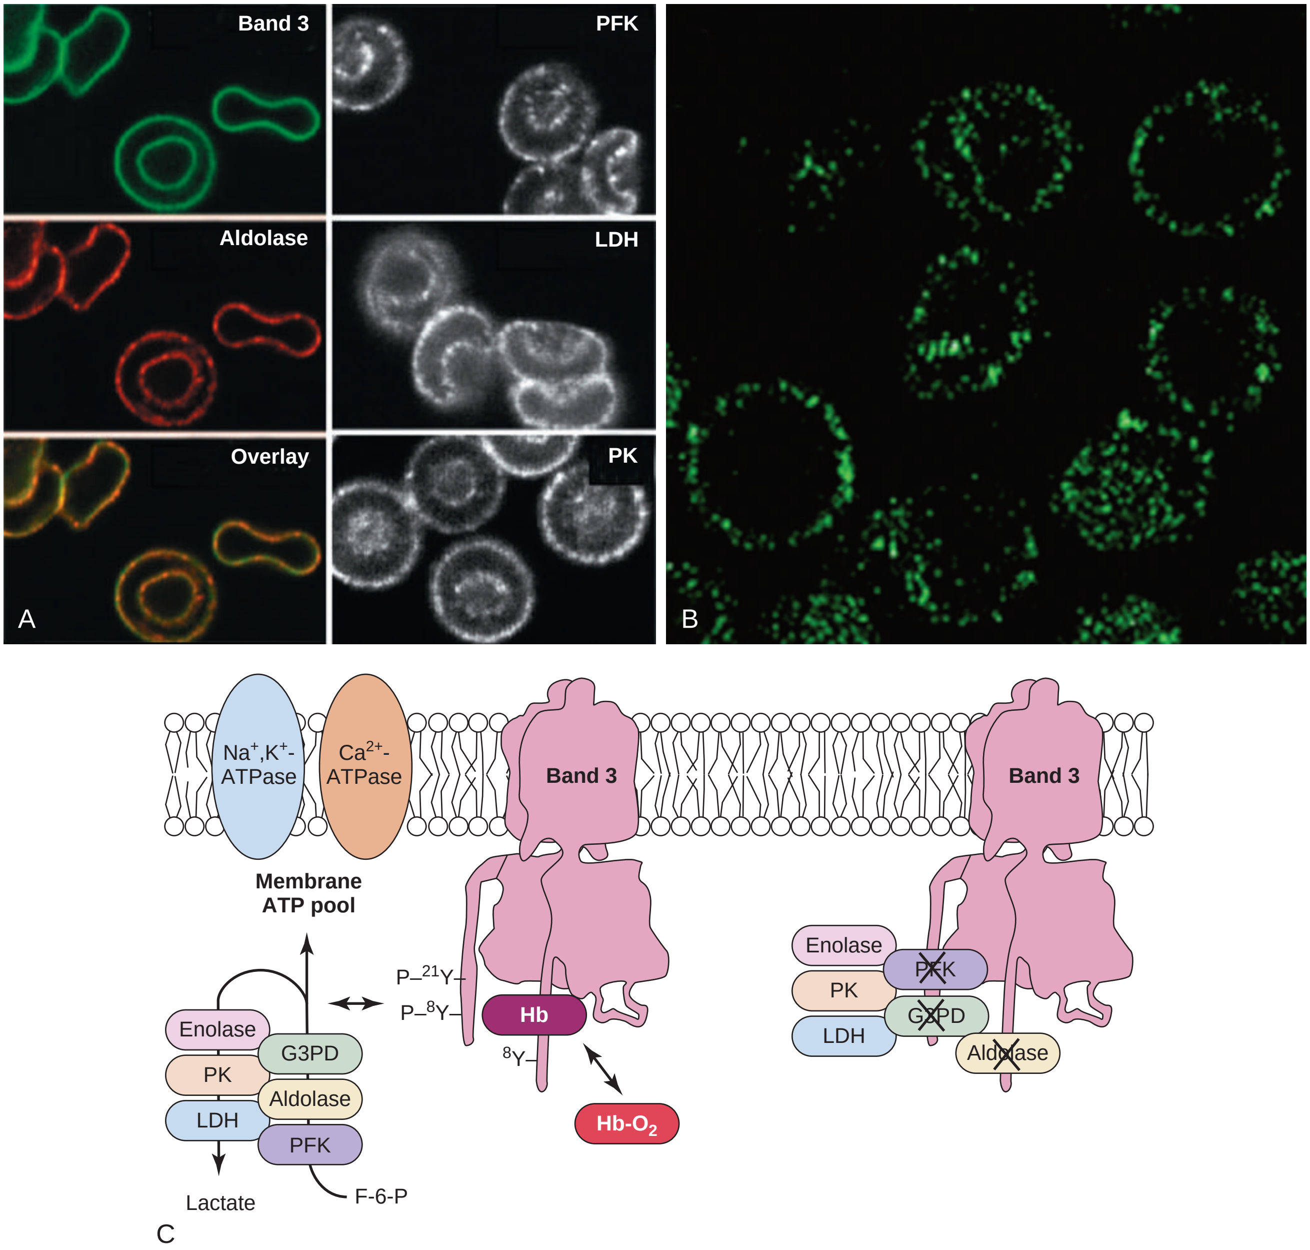

Figure 15-8 Glycolytic metabolon. **A,** Fluorescent imaging of band 3 and aldolase on the *left* and phosphofructokinase *(PFK)*, lactate dehydrogenase *(LDH)*, and pyruvate kinase *(PK)* on the *right*. Note that band 3 is uniformly and exclusively in the membrane whereas the five enzymes are mostly attached to the membrane (some cytoplasmic staining, especially for LDH) and have a punctate appearance as though they are clustered. Glyceraldehyde-3-phosphate dehydrogenase *(G3PD)* stains similarly but is not shown. Aldolase, PFK, and G3PD bind to band 3; PK and LDH do not. However, all are displaced by a fragment of the band 3–binding site, by phosphorylation of the site, or by deoxyhemoglobin, plus all can be cross-linked to one another, indicating that all are bound in a complex or "metabolon." **B,** Discrete, discontinuous submembrane pools of a fluorescent analogue of adenosine triphosphate *(ATP)*, synthesized by phosphoglycerate kinase. **C,** Schematic of the postulated glycolytic metabolon. The enzyme complex binds to the amino terminus of band 3 *(right)* and to a site near the junction between the cytoplasmic and membrane domains *(not shown)*. When the complex is bound to band 3 *(right)*, the enzymes are inactive. The complex can be displaced and activated *(left)* by phosphorylation of Tyr8 and Tyr21 on band 3 or by binding of deoxyhemoglobin. Some of the ATP produced is retained at the membrane and used by the Na^+,K^+-ATPase and Ca^{2+}-ATPase. *F-6-P,* Fructose-6-phosphate; *Hb,* hemoglobin. *(**A,** From Campanella ME, Chu H, Low PS: Assembly and regulation of a glycolytic enzyme complex on the human erythrocyte membrane.* Proc Natl Acad Sci U S A *102:2402–2407, 2005; **B,** From Chu H, Puchulu-Campanella E, Galan JA, et al: Identification of cytoskeletal elements enclosing the ATP pools that fuel human red blood cell membrane cation pumps.* Proc Natl Acad Sci U S A *109:12794–12799, 2012.)*

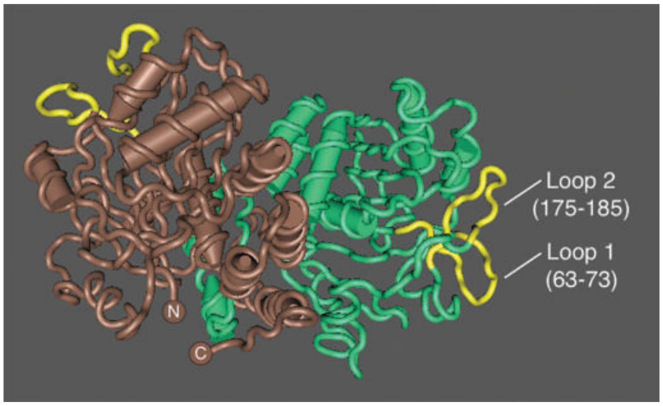

Figure 15-9 Structure of the band 3 cytoplasmic domain. The amino acid backbone of the band 3 dimer is shown. One monomer is *brown*, the other *green*. Note how the monomers interlock in the center. The two loops that protrude from the surface of the molecule to form the ankyrin-binding site (amino acids 63 to 73 and 175 to 185) are *yellow*.

band 3. First, blocking the N-terminus with an antibody inhibits ankyrin binding. Second, association of ankyrin with band 3 is blocked by phosphorylation of tyrosines 8 and 21, and, vice-versa, ankyrin binding prevents phosphorylation of these tyrosines. As mentioned earlier, deoxyhemoglobin also binds to the N-terminus. In doing so it displaces ankyrin and weakens the membrane.[210] Stefanovic and colleagues postulate that this could improve blood flow during brief periods of deoxygenation but might promote unwanted membrane vesiculation during prolonged deoxygenation, as in sickle cell disease.[210]

Ankyrin preferentially binds to band 3 "tetramers."[211,212] Whether band 3 spontaneously forms tetramers and then attracts ankyrin, stabilizing the tetramers, or whether ankyrin, which has two binding sites for band 3, independently binds two band 3 dimers (i.e., a "dimer of dimers") is unresolved. The fact that a stable subpopulation of band 3 tetramers can be isolated from nonionic detergent extracts of ghosts[213,214] argues for the former. The fact that at least one structure of the band 3/ankyrin complex precludes a tetramer[215] argues for the latter. It is estimated that 40% of band 3 is bound to ankyrin as tetramers (120,000 tetramers) whereas 60% exists as dimers (360,000 dimers).[213]

Protein 4.1R, which links the spectrin-actin–based skeleton to the plasma membrane in part via interactions with glycophorin C, binds to the cytoplasmic domain of band 3 at specific (I/L)RRRY sequences near the inner membrane surface (see Fig. 15-7).[216] The interaction is important because zebrafish with a severe hemolytic anemia due to lack of band 3 can only be rescued by band 3 that contains IRRRY sites.[217] Rescue is markedly reduced if mouse band 3 containing a mutation in either the LRRRY or IRRRY site is used and is nearly abolished if both sites are mutated. Because protein 4.1R and ankyrin compete for binding to band 3[218] and ankyrin binds exclusively to band 3 tetramers, it seems likely that protein 4.1R binds preferentially to dimeric band 3 (see Fig. 15-6).

Protein 4.2, a 77-kD peripheral membrane protein of the red cell, also interacts with the cytoplasmic domain of band 3. The binding site is not well defined. Red cells from patients with the cytoplasmic band 3 mutations Glu40→Lys, Gly130→Arg, and Pro327→Arg show some deficiency of protein 4.2, and the mutant band 3 molecules bind protein 4.2 poorly in vitro.[219] Pro327 and Gly130 are not too close to each other in the crystal structure of band 3 so either there is more than one binding site or one of the mutations induces more global effects on band 3 structure. It is not clear whether protein 4.2 preferentially binds to the ankyrin-linked band 3 tetramers or to band 3 dimers, but, as discussed later in the section on protein 4.2, it probably binds to both. Because protein 4.2 binds to the carboxy-terminus (C-terminus) of α spectrin, near the spectrin-actin junction, it appears that band 3 may attach the skeleton to the lipid bilayer at both the head end of spectrin, where ankyrin binds, and at the tail end, where actin, proteins 4.1R and 4.2, and adducin bind (see Fig. 15-6). Whatever the arrangements, protein 4.2 depends on band 3 to be expressed in the membrane. Membranes from band 3 knockout mice completely lack 4.2,[220] and membranes from 4.2 knockout mice are partially deficient in band 3.[221]

Adducin, is an actin-binding protein that caps actin filaments and enhances the binding of spectrin to actin. It is discussed later in the chapter. Adducin binds to the cytoplasmic domain of band 3 via its extended, flexible tail domain (see Fig. 15-6).[222] The tails of both α and β adducin bind band 3, but the free β-adducin tail domain disrupts red cell membrane morphology and stability more than the α-adducin tail,[222] suggesting it is the more important interaction physiologically. Mice lacking all adducins have a mild spherocytic hemolytic anemia but have normal amounts of band 3 and spectrin.[223]

Band 3 Tyrosine Phosphorylation Weakens Ankyrin Binding. Band 3 is phosphorylated on tyrosine residues 8, 21, 359, and 904 by p72Syk kinase[224-226] and to a less extent by Lyn kinase.[227] This displaces the glycolytic enzyme complex,[193,194] as noted earlier, but it also greatly weakens band 3/ankyrin binding, which in turn promotes band 3 diffusion within the lipid bilayer and red cell spiculation and vesiculation.[228] The effect on the interactions of band 3 with its other binding partners is unknown. In the basal state, band 3 tyrosines are unphosphorylated, owing to the action of phosphatases,[228] but they become phosphorylated after malaria invasion[225] and by oxidative damage, such as occurs in hemoglobinopathies[229] and glucose-6-phosphate dehydrogenase (G6PD) deficiency.[224,230]

Flexible Link between the Cytoplasmic and Membrane Domains. Kurtz and his colleagues have analyzed hundreds of high-resolution electron micrographs of single band 3 dimers and find that cytoplasmic and membrane domains orient differently in different molecules, strongly suggesting that the connecting region is flexible.[231] The fact that loss of a portion of this linker in Southeast Asian ovalocytosis (see Chapter 16) results in very rigid red cell membranes suggests that the link may be important in regulating red cell elasticity.

Kidney Band 3. Band 3 is also expressed in the basolateral membrane of the type A intercalated cells in the kidney collecting ducts where it collaborates in the excretion of H^+ and reclamation of HCO_3^-. The kidney isoform lacks the first 65 amino acids and does not bind ankyrin.[232]

Membrane Domain

The 52-kD Membrane Domain (Amino Acids 360 to 911) Contains an Anion Exchange Channel. The anatomy of the membrane domain of band 3 has been an active area of interest, with the goal of research efforts focused on understanding how the membrane domain's topology enables the 1.2 million channels in each red cell to exchange 10 to 30 billion HCO_3^- or Cl^- anions per second.[233,234] The 6 nm long × 11 nm wide × 7 nm deep[174] membrane domain contains numerous transmembrane and intramembrane helices, some of which are tilted in a V shape like they are in the bacterial ClC chloride channel.[174-176] Multiple topology models of the membrane domain have been derived over the years using different techniques to see which amino acids are accessible from the exterior and interior of the cell.[173,235-238] The latest and most plausible one is based on homology between band 3 and the ClC channel (see Fig. 15-7).[173]

Despite considerable effort, we still do not know which transmembrane segments form the anion channel or exactly how the channel functions. Residues in helices D, F, H, I, N, and R are predicted to contribute to the transport process.[173] The clustering of mutations responsible for various disorders of red cell membrane permeability between helices K and N suggests that region is also involved (see Fig. 16-35).

Carbonic anhydrase IV (CAIV), a GPI-linked protein, binds to the outside of the membrane domain,[239] probably just beyond the glycosylation site (Asn642) in the protein loop that connects helices I and J (see Fig. 15-7).

Carbonic anhydrase II (CAII) may[240] or may not[241] bind to band 3, on the C-terminal extension at the inside surface of the channel (see Fig. 15-7). Assuming it does, there is evidence that it increases HCO_3^-/Cl^- exchange[138,242,243] and helps create an acidic microdomain around band 3 during HCO_3^- transport.[244] The two carbonic anhydrases potentially form a CO_2/HCO_3^- transport metabolon with band 3.[138,239]

The Transport Channel Exchanges Chloride and Bicarbonate Rapidly (~20,000 to 50,000 Times per Second per Channel), Facilitating CO_2 Transport from the Tissues to the Lungs. In the peripheral tissues, CO_2 is either rapidly converted to HCO_3^- at the surface of band 3 by CAIV and enters the red cell via band 3 or it diffuses across the red cell membrane and is then converted to HCO_3^- by CAII. The H^+ by-product of the carbonic anhydrase reaction binds to hemoglobin and *facilitates* O2 release to the tissues (i.e., the Bohr effect). The whole process is reversed in the lungs (Fig. 15-10). As the red cell circulates, intracellular HCO_3^- is exchanged for extracellular chloride. As a result, HCO_3^- is transported in the plasma as well as within the red cell, which increases CO_2 transport from the tissues to the lungs by approximately 60%.[234] The HCO_3^-/Cl^- exchange is believed to occur by a "ping-pong" mechanism, whereby an intracellular anion enters the transport channel and is translocated outward and released, with the channel remaining in the outward configuration until an extracellular anion enters and activates the reverse cycle.[174,245]

Although HCO_3^- and Cl^- are the predominant physiologically relevant anions exchanged by band 3, the specificity of the channel is actually quite broad and larger anions such as sulfate, phosphate, pyruvate, and superoxide are also transported, albeit at much slower rates.[246]

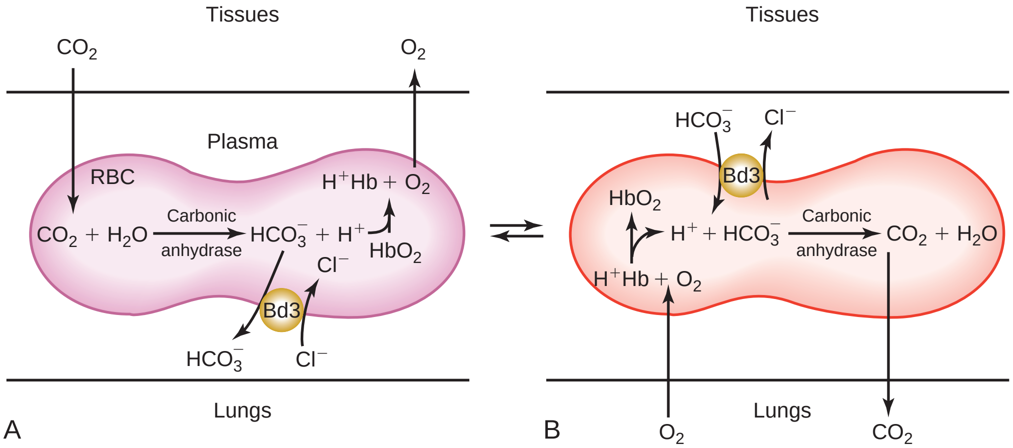

Figure 15-10 Function of band 3 in O_2 and CO_2 transport. **A,** Tissue CO_2 is converted into HCO_3^- and H^+ in the red cell by carbonic anhydrase. Band 3–mediated exchange of the HCO_3^- for Cl^- (Hamburger shift) allows HCO_3^- to be carried in the plasma as well as the red cell and increases CO_2 uptake by about 60%. H^+ binds to hemoglobin and facilitates O_2 release (Bohr effect) and tissue oxygenation. **B,** These processes are reversed in the lungs, which promotes hemoglobin oxygenation and release of CO_2. *(Modified from Weith JO, Anderson OS, Brahm J, et al: Chloride-bicarbonate exchange in red blood cells: physiology of transport and chemical modification of binding sites.* Philos Trans R Soc Lond [Biol] *299:383, 1982.)*

Several potent and experimentally useful inhibitors of band 3 anion transport are also known, with the most commonly employed being stilbene disulfonates, such as 4,4′-diisothiocyanostilbene-2,2′-disulfonate (DIDS).[246]

The Extracellular Surface of the Band 3 Membrane Domain is the Site of Specific Blood Group Antigens. Asn642, located in the extracellular loop between helices I and J, is derivatized with a complex lactosaminoglycan that is variable in length and contains the I/i blood group antigens (see Fig. 15-7).[247] In fetal cells, the carbohydrate chain is unbranched and has i specificity,[248] whereas in adults there is a branched structure that yields I reactivity.[249] Extracellular domains of band 3 also contain the antigens of the Diego and at least 13 other blood groups.[250-258]

The Integral Membrane Protein Glycophorin A (GPA) and the Membrane Domain of Band 3 are Functionally Associated. The Wright (Wr) blood group antigen is formed by the association of GPA and band 3.[258] Glu658 in band 3 is required for normal expression of this blood group antigen,[259] and an Ala65→Pro mutation in GPA causes aberrant Wright antigen expression.[260] Furthermore, a monoclonal antibody directed against the Wr^b antigen immunoprecipitates both proteins,[261] and anti-GPA antibodies immobilize both GPA *and* band 3 in the membrane.[262]

GPA also has a chaperone-like role in bringing band 3 to the plasma membrane. The coexpression of GPA and band 3 facilitates the expression of band 3,[263] red cells lacking band 3 also lack GPA,[264] and mutant band 3 molecules that are stuck in the endoplasmic reticulum can be rescued by coexpression of the mutant band 3 with GPA.[265] GPA also enhances band 3 transport.[263] SO_4^{2-} transport is diminished 60% in the absence of GPA.[266]

Organization of Band 3 in the Membrane

A variety of evidence supports the concept that band 3 exists in three populations: one tethered to spectrin via ankyrin, one attached to the spectrin/actin junctional complexes via adducin and protein 4.1R, and a freely diffusing population.

Band 3 Mutations

Mutations in band 3 are known to cause hereditary spherocytosis, hereditary stomatocytosis, hereditary cryohydrocytosis, Southeast Asian ovalocytosis, hereditary distal renal tubular acidosis and, in one case, hereditary acanthocytosis. These are discussed in the various sections of Chapter 16 and illustrated in Figures 16-10 and 16-35. Incomplete processing of the band 3 N-linked lactosaminoglycan moiety occurs in congenital dyserythropoietic anemia type II (CDA II or hereditary erythroblastic multinuclearity with positive acidified serum lysis test [HEMPAS]), which is discussed in Chapter 7.

Band 3 and Malaria

Plasmodium falciparum parasites are believed to invade red cells via two distinct pathways, one that is dependent on the sialic acids of GPA or glycophorin C (GPC), and a second, a sialic-acid independent, pathway that is linked to band 3. Expression of a parasite protein called PfRh4 correlates with switching to the sialic acid–independent pathway.[267] Liposomes containing purified band 3 inhibit invasion,[268] as does a monoclonal antibody against extracellular epitopes of band 3.[269] Peptides corresponding to the two of the surface loops of band 3 also partially block invasion,[270] suggesting that these regions serve as receptors. MSP1 (*P. falciparum* merozoite surface protein 1) furnishes the ligand.[270]

Glycophorins

The glycophorins[271] are a family of integral membrane glycoproteins that account for about 90% of the surface charge of the red cell. The extracellular domains of glycophorins contain abundant negatively charged sialic acid molecules that keep red cells from adhering to each other and to vessel walls. Surface epitopes of the glycophorins generate the blood group antigens in the MNSs system. Glycophorins also serve as receptors for infective agents, such as *P. falciparum,* and function as chaperones, facilitating the targeting of specific integral membrane proteins to the plasma membrane. The glycophorins belong to the broad family of integral membrane proteins that pass through the lipid bilayer as a single α helix.

Glycophorin A

The glycophorin A (GPA) gene *(GYPA)* is located on the long arm of chromosome 4 (4q31) and is increasingly expressed throughout erythroid development.[168] It encodes a 36-kD protein that is the major sialoglycoprotein of the red cell (~10^6 copies per cell). It was the first membrane protein to have its complete amino acid sequence determined. Amino acids 1 to 61 form the extracellular N-terminal domain, which contains a complex oligosaccharide attached to Asn26[272] and 15 serine or threonine O-linked tetrasaccharides with sialic acid moieties (Fig. 15-11, *A*).[273] The carbohydrate component of GPA accounts for 60% of its molecular mass. Experimentally, the glycophorins run anomalously on SDS gels because the abundant carbohydrate interferes with detergent binding. In addition, the carbohydrate interferes with Coomassie Blue staining, such that special stains (e.g., periodic acid–Schiff) are required to visualize the glycophorins. The N-terminus of GPA contains the site of the MN blood group antigens. Amino acids 1 and 5 along with the sialic acid residues on adjacent O-linked tetrasaccharides dictate the antigenicity.[274] Amino acids 1 and 5 are serine and glycine in MM red cells; leucine and glutamic acid in the corresponding positions characterize NN cells. Amino acids 72 to 95 form the transmembrane domain of GPA, which traverses the lipid bilayer as a single α helix. The membrane domain interacts with negatively charged lipids, such as PS and PI at the internal end (Fig. 15-11, *A*).[275,276] The α-helical transmembrane domains self-associate to form a dimer[277,278]: Ile76, Val80, and Val84 on the α helix of one monomer interface with Leu75, Gly79, Gly83, and Thr87 on the second monomer.[279] The extracellular domain also contributes to this dimeric interaction,[280] which is strong enough to resist dissociation by detergents.

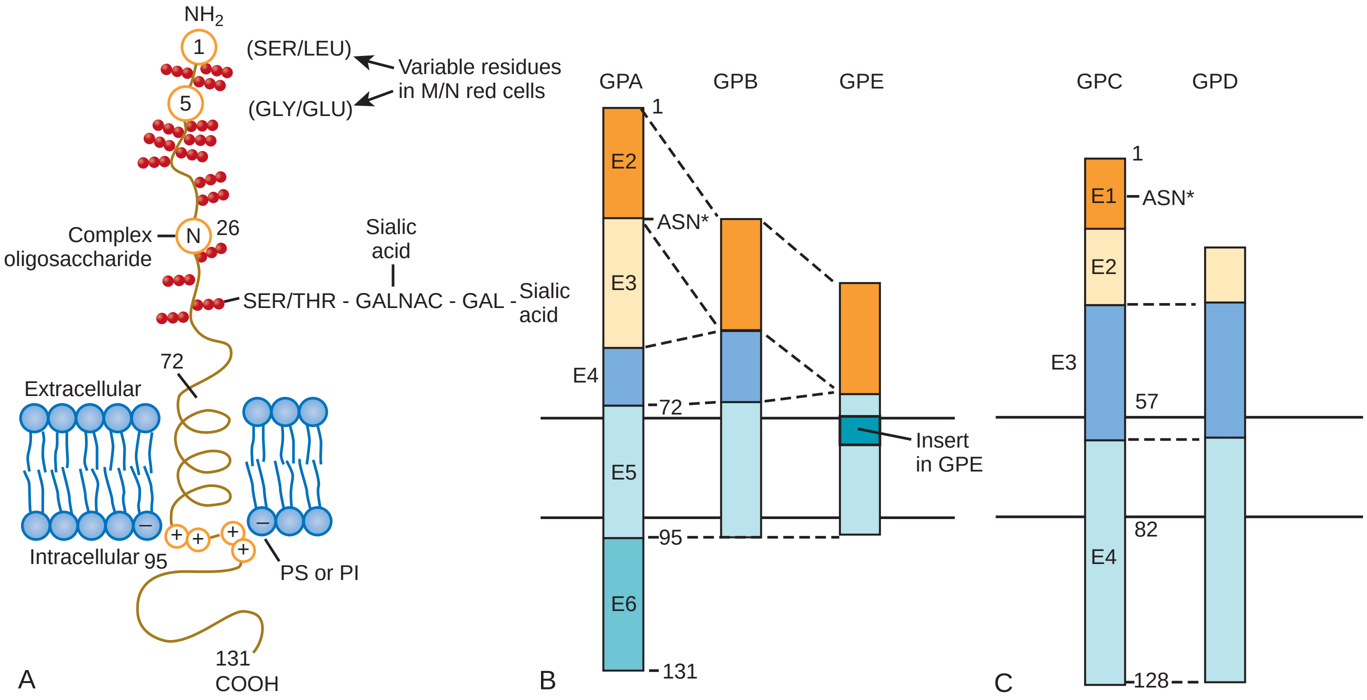

Figure 15-11 Structural model of red cell glycophorins. **A,** Organization of glycophorin A *(GPA)*, the major red cell sialoglycoprotein. The external domain has 15 tetrasaccharides attached to serine or threonine residues and one complex oligosaccharide attached to asparagine 26. Residues 1 and 5 are Ser and Gly in M red cells and Leu and Glu in N cells. **B,** Schematic representation of the domain combinations of GPA, glycophorin B *(GPB)*, and glycophorin E *(GPE)*. Each *box* represents the portion of each protein encoded by a specific exon or insertion sequence. ASN* is the site of attachment of the complex carbohydrate. **C,** Schematic representation of the domains contributing to glycophorin C *(GPC)* and glycophorin D *(GPD)*. *PI,* Phosphatidylinositol; *PS,* phosphatidylserine. *(Modified from Becker PS, Lux SE: Disorders of the red cell membrane skeleton: hereditary spherocytosis and hereditary elliptocytosis. In Scriver CR, Beaudet AL, Sly WS, et al, editors:* The metabolic basis of inherited disease, *7th ed. New York, 1995, McGraw-Hill; and Fukuda M: Molecular genetics of the glycophorin A gene cluster.* Semin Hematol *30:138, 1993.)*

As noted in the earlier section on band 3, the cytoplasmic domain of GPA (amino acids 96 to 131) enhances the trafficking of band 3 to the membrane[280] and increases band 3 anion transport.[266] Conversely, GPA is dependent on band 3 for trafficking or for stable incorporation in the red cell membrane, because mice that lack band 3 also lack GPA.[264]

Interestingly, treatment of red cells with antibodies (or monovalent Fab fragments) to GPA causes GPA to bind to the membrane skeleton and makes the cells rigid.[281] These changes depend on the cytoplasmic domain of GPA, suggesting that it binds to the membrane skeleton in response to a transmembrane signal initiated by antibody treatment.[282] Hypothetically, cellular rigidity induced by adherence of pathogens to glycophorins might enhance reticuloendothelial clearance of infected cells[282] or impede invasion by parasites, but whether it does so is untested.

GPA is a specific marker for the erythroid lineage and is detectable from the proerythroblast stage.[168]

Glycophorin B

The glycophorin B (GPB) gene *(GYPB)* lies just downstream of GPA on chromosome 4.[283,284] The first 26 amino acids of the extracellular N-terminal domain are almost identical to the N blood group form of GPA except that GPB lacks the N-linked complex oligosaccharide (see Fig. 15-11, *B*).[274] In addition to N–blood group reactivity, GPB carries the S, s, and U blood group antigens, with the S and s antigens differing by substitutions at residue 29 (S = Met, s = Thr).[285] Distally, GPB is missing a portion of the extracellular domain corresponding to exon 3 of GPA and lacks almost all of the cytoplasmic domain. Whether GPB exists as homodimers, as heterodimers with GPA, or as both is not known.

GPB may interact with the RhAG protein in the Rh complex (to be discussed) because RhAG is hyperglycosylated in GPB-null individuals[286] and because GPB expression is decreased in Rh_{null} patients.[287]

Glycophorins C and D

Glycophorins C and D (GPC, GPD) have a general domain structure similar to GPA and GPB (see Fig. 15-11, C) but are encoded by a distinct gene *(GYPC)* located on chromosome 2 (2q14-2q21).[288] The gene is maximally expressed in mid-erythropoiesis.[168] GPD is generated from the same mRNA as GPC by means of an alternate initiation codon.[289] GPC is a 32-kD protein bearing one N-linked oligosaccharide and approximately 12 O-linked oligosaccharides in the N-terminal, extracellular domain. Amino acids 41 to 50 of the extracellular domain contain the Gerbich blood group antigens. Like GPA and GPB, the transmembrane domain passes through the lipid bilayer as a single α helix. The cytoplasmic domain of GPC forms a ternary complex with protein 4.1R and p55

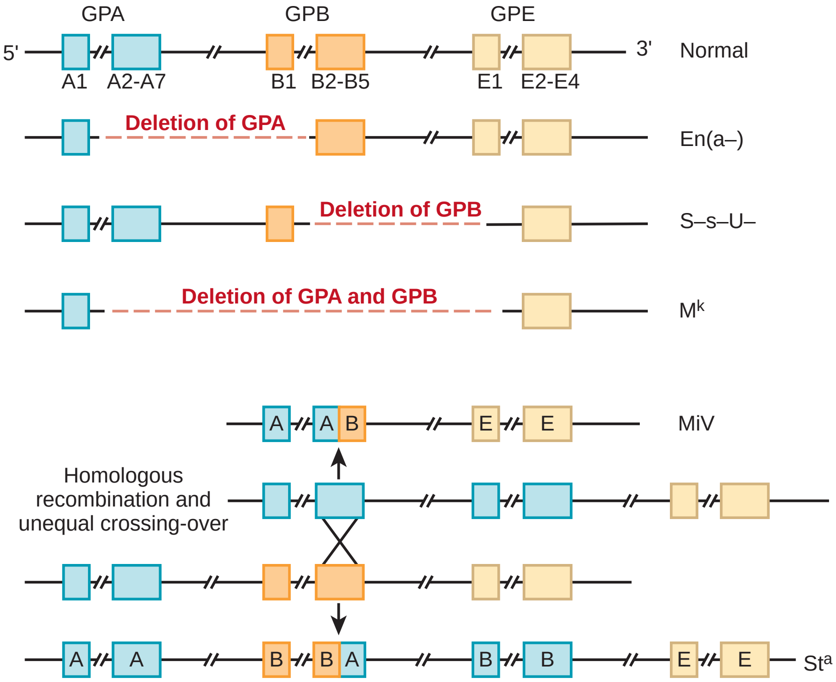

Figure 15-12 Glycophorin variants. Organization of the glycophorin A *(GPA)*, B *(GPB)*, and E *(GPE)* genes on chromosome 4 and probable deletions in the En(a–), S–s–U–, M^k, Miltenberger type V *(MiV)*, and Stones *(St^a)* variants. The MiV and St^a variants arise from unequal crossing over, analogous to the Lepore hemoglobins. In MiV red cells the normal GPB gene is replaced by a fusion gene (Lepore-type recombination). In St^a erythrocytes the product of the reciprocal exchange is inserted between the GPA and GPB loci but no normal genes are lost (anti–Lepore-type recombination). *(Modified from Vignal A, London J, Rahuel C, et al: Promoter sequence and chromosomal organization of the genes encoding glycophorins A, B, and E.* Gene *95:289–293, 1990.)*

and helps attach the spectrin-actin–based skeleton to the plasma membrane (see Fig. 15-6). The 30-kD membrane-binding domain of protein 4.1R interacts with amino acids 82 to 98 of GPC and the corresponding residues 61 to 77 of GPD.[290] p55 is a member of the membrane-associated guanylate kinase (MAGUK) family of proteins and contains a single PDZ domain that binds to GPC at residues 112 to 128 and to GPD at the corresponding amino acids 91 to 107.[290,291] The ternary complex of GPC/GPD, protein 4.1R, and p55 aids in maintaining red cell membrane deformability and mechanical stability. Unlike GPA and GPB, GPC and GPD are expressed in a variety of tissues, although at lower levels than in erythroid cells and with different glycosylation patterns.[292,293] They may have analogous functions in the membrane mechanics of nonerythroid cells.

Glycophorin E

The glycophorin E (GPE) gene *(GYPE)* lies just downstream of GPB on chromosome 4 and encodes a putative 78-amino acid protein with structural similarities to GPB (see Fig. 15-11, *B*).[294] The extracellular domain of GPE corresponds to exon 2 of GPB, but the amino acid sequence specifies blood group M rather than N.[294] The transmembrane domain contains an 8-amino acid insertion. Like GPB, GPE has a markedly truncated cytoplasmic domain. GPE is believed to have arisen by gene duplication of GPB, which in turn derived from ancestral duplication of GPA.[284] Thus GPA, GPB, and GPE define an erythroid-specific family of integral membrane sialoglycoproteins. The level of expression of GPE and its function, if any, are unknown and it may only be a pseudogene.

Glycophorin Mutations

Defects in GPA, GPB, and GPE Give Rise to Nearly 40 Variant Phenotypes of the MNS Blood Group System.[295] Complete loss of GPA, GPB, or both, often by gene deletion from unequal recombination of the neighboring loci, gives rise to En(a–), (S–s–), and M^kM^k red cells, respectively (Fig. 15-12). En(a–) red cells, for example, are completely deficient in GPA and have weak MN blood group antigens.[296,297] The affected red cells compensate for a potential 60% loss of surface charge by increasing the glycosylation of band 3, such that the overall surface charge is only reduced by approximately 20%.[298] Given the proximity and homology of GPA, GPB, and GPE genes, hybrid glycophorin molecules may be generated by recombination events during meiosis. In the MiV variant, for example, Lepore-like recombination yields a fusion gene containing the N-terminus of GPA and C-terminus of GPB.[299] In the St^a variant, anti-Lepore recombination produces the reverse hybrid (N-terminal GPB with C-terminal GPA), which is inserted between the normal GPA and GPB genes, neither of which is lost.[299] Interestingly, none of the GPA and GPB variants produces detectable changes in erythropoiesis or in the shape, function, or life span of the affected red cells. Rare individuals with complete absence of GPA and GPB apparently exhibit no erythrocyte abnormalities.[300]

Similarly, GPA knockout mice have a normal phenotype except that they have 60% less O-linked oligosaccharides than normal red cells.[301] Thus either GPA, GPB, and GPE do not serve any critical basal functions in red cells or such functions are subsumed by other protein(s), such as GPC or band 3, when GPA, GPB, and GPE are deficient. If GPA really has no nonredundant function, it is surprising that deletions and other mutations are not more common, because GPA is a major receptor for *P. falciparum* malaria (see later) and must be under intense evolutionary pressure.

Variations in GPC and GPD Affect the Gerbich Antigen System. Mutations in the extracellular domain of GPC and GPD alter the antigenicity of red cells (Gerbich antigen system) but do not affect cellular mechanical properties.[293,302] In contrast, in the Leach phenotype there is complete loss of GPC and GPD secondary to deletion of exons 3 and 4[303,304] or a frameshift mutation.[304] Affected individuals do not have significant hemolysis, but their red cells are slightly elliptocytic[305,306] and exhibit decreased membrane deformability and mechanical stability,[302,307,308] probably because GPC-deficient cells are partially deficient in protein 4.1R and p55.[309] Individuals with homozygous protein 4.1R deficiency have a more profound deficiency of GPC (~70%) in their elliptocytic red cells,[310,311] underscoring that the cellular content of each component of the ternary complex depends on the expression level of the others.

Glycophorins as Receptors for Malarial Invasion

Invasion of red blood cells by *P. falciparum* malaria occurs by multiple different pathways, depending on the species, and involves all of the different glycophorins. GPA serves as the receptor for the parasite ligand EBA-175.[312] A membrane fraction containing GPA or antibodies to GPA inhibits malarial invasion,[313] and erythrocytes lacking GPA resist invasion.[314,315] The binding specificity of EBL-175 is determined by the Neu5Ac-(α2,3)-Gal moiety on the O-linked tetrasaccharides of GPA[312] and on the amino acid sequence, which places the sugars in the proper configuration.

GPB-dependent invasion is also sialic acid dependent but is believed to utilize another parasite ligand.[316]

GPC appears to be the receptor for a third sialic acid–dependent pathway for *P. falciparum* malaria.[317-320] GPC/GPD-deficient red cells (Leach blood group phenotype) and protein 4.1R–deficient red cells (which partially lack GPC) resist malarial invasion in vitro,[317] and up to 50% of the Melanesian population in the malarious coastal areas of Papua New Guinea have red blood cells that are Gerbich blood group negative, owing to a deletion in the third exon of the GPC gene.[318] GPC binds the *P. falciparum* ligand EBA-140, which is also called BAEBL.[319-321]

In addition, there are *P. falciparum* strains that invade neuraminidase-treated red cells (i.e., cells lacking sialic acid),[322,323] so a sialic acid/glycophorin-independent mechanism(s) for malarial invasion also exists.[267] One such mechanism may involve merozoite adhesion to band 3.[268]

The existence of so many ways for *P. falciparum* to invade erythrocytes and the ability to switch between invasion pathways obviously complicates efforts to create a malarial vaccine.

Other Integral Membrane Proteins

Although band 3 and the glycophorins are the major integral membrane constituents of the red cell membrane, a large number of other integral membrane proteins with specific functions have also been identified and characterized.

Basigin

Basigin, or CD147, is a glycosylated integral membrane protein belonging to the immunoglobulin superfamily.[324] The common 269-amino acid isoform basigin-2 has two external immunoglobulin domains and a single transmembrane domain. It binds to and regulates the expression of monocarboxylic acid transporters (MCTs). A complex between basigin, MCTs, and CD44 occurs in breast cancer cells and probably in erythroid cells. Basigin has many functions in cancer, infection, inflammation, and development, but in the red cell its known functions are that it carries the common OK blood group antigen and serves as the receptor for the *P. falciparum* protein PfRh5.[324,325] Unlike the glycophorins and band 3, which are required for the adhesion of some parasites but not others, it appears that basigin and PfRh5 are required for all *P. falciparum* strains.[320,324] PfRh5 cannot be deleted from the pathogen,[326] and antibodies to PfRh5 block invasion of all strains,[327] as do antibodies to basigin or knockdown of the protein in red cells.[325] This makes the PfRh5/basigin complex a prime target for a malarial vaccine.

Rh Proteins (RHD, RHCE, and RhAG)

The Rh blood group system comprises at least 40 independent antigens carried by two nonglycosylated, palmitoylated proteins encoded by two homologous genes, *RHD* and *RHCE*, located on chromosome 1.[328-330] *RHCE* encodes the CcEe set of antigens, and *RHD* encodes the D antigen. Rh antigen expression at the red cell surface requires the presence of the Rh-associated glycoprotein (RhAG), which exhibits 36% sequence identity with Rh proteins and is encoded by a gene located on chromosome 6. There are 100,000 to 200,000 copies of RhD, RhCE, and RhAG per cell, and they probably form a heterotrimer based on the structure of the kidney isoform of RhAG.[331] They are each predicted to have 12 membrane-spanning domains. In addition to the interaction between the three Rh subunits, the Rh core complex also contains several other proteins[330]—LW glycoprotein (ICAM-4), integrin-associated protein (IAP, CD47), GPB, and protein 4.2. The core complex is part of the ankyrin complex (see Fig. 15-6).[332]

The RhAG protein functions as an NH_4^+-NH_3 transporter in mouse and human red cells[333-337] and can complement defects in ammonium transport in yeast.[338] It may also be partly responsible (along with aquaporin-1) for the exceptionally high permeability of CO_2 in the erythrocyte.[339,340] And some researchers speculate that it may serve as a channel for nitric oxide.[341] The importance of the Rh complex in regulating red cell membrane structure is revealed by the altered phenotype of Rh_{null} red cells, which exhibit stomatocytic morphology with loss of membrane surface area, cell dehydration, cation permeability abnormalities, and shortened red cell survival, leading to a mild compensated hemolytic anemia.[342] The Rh_{null} syndrome is discussed in Chapters 16 and 36.

Defects in RhAG that block the ammonium channel and make it highly permeable to Na^+ ions are responsible for overhydrated hereditary stomatocytosis (see Chapter 16).[343,344]

Kidd Glycoprotein

The Kidd glycoprotein (Jk antigen, SLC14A1) is the urea transporter in the red cell membrane and the kidney.[345] The human Kidd glycoprotein gene is located on chromosome 18q12.3 and encodes a 389-amino acid polypeptide with 10 membrane-spanning domains. There are roughly 10,000 copies of Kidd glycoprotein per cell, and the protein carries the antigens of the Kidd blood group system.[346] The Kidd glycoprotein forms the urea transporter in red cells, which functions by rapidly transporting urea into and out of red cells as they pass through the high urea concentration in the renal medulla.[347] Urea transport across $Kidd_{null}$ red cell membranes is approximately a thousand times slower than across normal membranes.[348] However, no changes in red cell shape or survival have been noted in persons who lack the Kidd glycoprotein.

Kell Glycoprotein

Kell glycoprotein is a 93-kD (732 amino acids) single-pass type II membrane protein encoded by a gene on chromosome 7q34.[349] It is a zinc endopeptidase that functions as an endothelin-3–converting enzyme on the erythrocyte surface.[350] It can also cleave the precursors of endothelin-1 and endothelin-2, but much less effectively. Because endothelins are potent vasoactive peptides, it is believed the Kell glycoprotein may be involved in regulation of vascular tone. There is evidence that endothelin-3 may also activate Ca^{2+}-ATPase in the red cell.[351] The Kell glycoprotein carries the antigens in the Kell blood group system. Isolated Kell glycoprotein deficiency does not alter red cell life span or morphology.[352]

Kx Protein

The Kx protein is a 37-kD protein (444 amino acids) with 10 membrane-spanning domains that is encoded by a gene *(XK)* on the short arm of the X chromosome,[353] The Kx protein carries the Kx blood group antigen. In the red cell membrane the Kx protein is covalently linked to the Kell glycoprotein by a disulfide bond.[354] The Kx/Kell complex is part of a larger complex of proteins that are located at the spectrin/actin/protein 4.1R junctions (see Fig. 15-6). The Kx protein has structural but not sequence similarity with a family of proteins involved in transport of neurotransmitters; however, its transport substrate(s) have not been defined. Experiments on red cells from Kell, Kx, and Kell/Kx knockout mice suggest that Kell and Kx affect Ca^{2+} and Mg^{2+} homeostasis and red cell volume.[351] Whether this is a direct or indirect effect is not known. Unlike isolated Kell deficiency, which has no evident phenotype, lack of the Kx protein in McLeod syndrome results in acanthocytic red cells, compensated hemolytic anemia, and, in later life, muscle wasting and choreiform movements. McLeod syndrome is discussed in Chapter 36.

Duffy Antigen/Chemokine Receptor

The Duffy blood group, atypical chemokine receptor (DARC or Fy antigen), is a promiscuous chemokine receptor[355] that binds a variety of proinflammatory cytokines of both the C-X-C class (acute inflammation) and the C-C class (chronic inflammation), including interleukin-8, MGSA (melanoma growth stimulatory activity), MCP-1 (monocyte chemotactic protein 1), and RANTES (regulated on activation, normal T-cell expressed and secreted). The *DARC* gene is located on chromosome 1q23.2 and encodes a 338-amino acid polypeptide with seven membrane-spanning domains.[356] There are 6,000 to 13,000 copies of DARC per cell and the protein carries the antigens of the Duffy (Fy) blood group system. DARC is the receptor for the human malarial parasites *Plasmodium vivax* and *Plasmodium knowlesi.* Duffy-deficient red cells, Fy(a–b–), which are common in individuals from Central and West Africa, are refractory to invasion by most,[357] but not all,[358] strains of *P. vivax*. The Duffy phenotype Fy(a+b–) also provides considerable protection.[359] On the other hand, DARC is necessary for platelet killing of *P. falciparum* malaria.[360] Platelet factor 4, a cytokine released from activated platelets, binds to the DARC and kills the parasite. The function of DARC in normal red cell physiology remains to be defined.

Lutheran Glycoprotein/Basal Cell Adhesion Molecule

The Lutheran blood group (Lu) resides on the basal cell adhesion molecule (BCAM), which belongs to the immunoglobulin superfamily and is the receptor on erythroid cells for the extracellular matrix protein laminin.[361-364] The Lu/BCAM glycoprotein consists of five disulfide-bonded extracellular immunoglobulin superfamily domains, a single hydrophobic transmembrane domain, and a short cytoplasmic tail. Two isoforms of this membrane protein (85-kD and 78-kD isoforms) are expressed by alternative splicing of a single gene located on human chromosome 19q13.32 and are distinguished by differences in their cytoplasmic domains—the 78-kD isoform has a truncated cytoplasmic tail. Both isoforms bind laminin. Binding is stimulated by epinephrine and is dependent on phosphorylation of Lu/BCAM by protein kinase A.[365,366] There are 1500 to 8000 copies of Lu glycoprotein on the mature red cell. Lu/BCAM directly interacts with the fourth spectrin repeat of α spectrin.[367,368] Disruption of this linkage enhances red cell adhesion to laminin[364] and is observed in hereditary spherocytes.[369] Increased laminin binding by red cell Lu/BCAM also seems to be important in the adhesion of sickle red cells.[370] The interaction between the $\alpha 4\beta 1$ integrin on sickle cells and the Lu/BCAM protein on endothelial cells may also be important.[370,371] Hydroxyurea decreases the phosphorylation of Lu/BCAM and decreases the laminin adhesion of sickle cells.[366] Constitutive Lu/BCAM phosphorylation mediates the increased adhesion of red cells to laminin in polycythemia vera and may contribute to the enhanced risk for thrombosis in that disease.[372] The Lu/BCAM-spectrin interaction is also involved in actin cytoskeleton dynamics in nonerythroid cells and is required for actin stress fiber formation.[373]

About 1 person in 5000 inherits the In(Lu) genotype,[374] which partially suppresses expression of Lu^a and Lu^b and is the most common cause of the null Lutheran phenotype, Lu(a–b–). In(Lu) is not a dominantly acting inhibitor as originally believed but is caused by inactivating mutations in one of the two *KLF1* genes or rarely GATA-1.[375,375a] KLF1 encodes EKLF, a transcription factor that controls many erythroid genes and is critical in erythroid development. Patients with the Lu(a–b–) phenotype due to In(Lu) have abnormally shaped red cells but no hemolysis.[376] The morphology varies from normal or mild poikilocytosis to acanthocytosis.

LW Glycoprotein

The LW glycoprotein (also termed ICAM-4)[377,378] also belongs to the immunoglobulin superfamily.[379] The glycoprotein carries the Landsteiner-Weiner (LW) blood group and consists of two extracellular immunoglobulin-like domains that show very strong sequence homology with the protein superfamily known as intracellular adhesion molecules (ICAMs). The 37- to 43-kD LW glycoprotein is encoded by a gene on chromosome 19p13.2. There are approximately 4000 copies of LW glycoprotein on the mature red cell. Preliminary evidence suggests that extracellular domains of LW glycoprotein can interact with integrins LFA1 (CD11/CD18)[380] and α4β1 and αV integrins.[381] Like Lu/BCAM, LW glycoprotein is activated by epinephrine and may also play a role in adhesion of sickle cells by directly increasing the binding of sickle cells to endothelium[382] and by indirectly activating lymphocytes and monocytes and increasing their attachment to vessel walls.[383]

CD47

CD 47, or integrin-associated protein (IAP), is a ubiquitously expressed, highly glycosylated five-span transmembrane protein with a single extracellular immunoglobulin domain and a small intracellular domain. It is widely distributed and is involved in a range of cellular functions, including apoptosis, proliferation, phagocytosis, adhesion, angiogenesis, inflammation, and cell migration.

There are about 17,000 CD47 molecules per erythrocyte.[141] Part of the CD47 is attached to the membrane skeleton and part is mobile and able to cluster.[384] Human CD47 interacts with the Rh protein complex and with protein 4.2. Reduction of protein 4.2 or band 3 leads to marked reduction in CD47 (see later section on protein 4.2).[384-386] The human RhCE protein is also crucial for CD47 expression because red cells that lack Cc and Ee antigens have a 75% reduction in CD47.[385]

In the mature red cell, CD47 may function as a marker of “self.” It interacts with the inhibitory receptor SIRPα (signal regulatory protein α, CD172a) on macrophages and inhibits phagocytosis.[387] Mouse red cells that lack CD47 are rapidly cleared from the blood by splenic macrophages.[387] The CD47-SIRPα interaction blocks phagocytic signaling from complement receptors, Fcγ receptors, and low-density lipoprotein (LDL) receptor–related protein-1. It does not inhibit scavenger receptors.[388,389] Enhancing the interaction offers therapeutic promise in autoimmune hemolytic anemias and thrombocytopenias but so far has not been achieved. Interestingly, attaching peptides that contain the CD47 “self” signal to nanoparticles prolongs their life in the circulation, enhancing their utility in drug delivery or imaging.[390]

Aquaporins

Aquaporin-1 (AQP1), a 28-kD channel-forming protein, is the major water channel in red cells.[383] The human aquaporin-1 gene *(AQP1)* is located on chromosome 7p14 and encodes a 269-amino acid polypeptide with six membrane-spanning domains. Besides red cells, AQP1 is also expressed in the kidney and in the endothelial cells in lung. There are 120,000 to 160,000 copies of AQP1 per cell, and the protein carries the antigens of the Colton blood group. It exists as a tetramer in the red cell membrane, and the crystal structure of the protein is known.[391] AQP1 can be cross-linked to stomatin in red cell membranes,[392] which suggests at least some of it resides in lipid rafts. Human red cells lacking AQP1 exhibit markedly reduced osmotic water permeability. Humans with complete deficiency of AQP1 have defective urinary concentrating ability as well as decreased pulmonary vascular permeability.[393,394] AQP1 knockout mice appear normal but become severely dehydrated and lethargic compared with control mice after water deprivation for 36 hours.[395] Interestingly, implanted tumors grow very poorly in AQP1(–/–) mice because of reduced vascularity and very poor cell migration.[396] These studies show that AQP1 also has an unexpected role in cell migration and thus in angiogenesis and wound healing. There is evidence that AQP1 also facilitates CO_2[397-400] and perhaps NH_3[400] transport across the red cell membrane.

Aquaporin-3 (AQP3) is the glycerol permeability channel in human red cells and carries the high-frequency blood group antigen GIL.[401] Humans lacking the channel are asymptomatic.[401] In mice, AQP3 is not expressed in red cells and aquaporin-9 (AQP9) is the glycerol channel.[402] AQP9-deficient mice survive longer during the initial phase of mouse malaria,[402] perhaps because plasma glycerol is an important substrate for lipid biosynthesis in malarial parasites.

Stomatin

Stomatin or band 7.2b (gene name *EPB72*), is a 31.5-kD integral membrane protein (approximately 28-kD on SDS gels).[403-406] It is a positively charged, homooligomeric (estimated 9 to 12 subunits), phosphorylated (cyclic adenosine monophosphate [cAMP]–dependent kinase), palmitoylated integral membrane protein with a single transmembrane helix, a small external segment, and a relatively large cytoplasmic domain.[403,405-408] It is present in all tissues and is found throughout evolution. As noted earlier, it is located, at least in part, in membrane lipid rafts.[99,100] Stomatin is a member of a protein superfamily—the PID superfamily, which stands for proliferation ion and death. Red cells contain other members of this family, such as SLP-2[409] and STORP,[410] but nothing is known about their functions or interactions.

Stomatin normally binds to the major glucose transporter, Glut1 (or SLC2A1), which also resides in lipid rafts,[411,412] and to band 3 and AQP1.[392] The site of binding on band 3 is unknown. In human red cells it switches Glut1 to an L-dehydroascorbic acid transporter (see following section).[413] It may also interact with peroxiredoxin-2 (see later section),[414] which itself attaches to band 3 (see Fig. 15-6).[183] Stomatin is interesting because it is diminished by 95% to 98% in the classic type of hereditary stomatocytosis, a severe hemolytic anemia characterized by red cell membranes that are extremely leaky to Na^+ and K^+ ions. The protein and its relationship to the disease are discussed in "Overhydrated Hereditary Stomatocytosis" in Chapter 16.

Glucose Transporter 1

Glucose transporter 1 (Glut1, SLC2A1)[415,416] is a 492-amino acid integral membrane glycoprotein that runs as a diffuse 45- to 65-kD band on SDS gels owing to heterogeneous glycosylation. It is one of the most abundant proteins in the red cell membrane, with more than 200,000 copies per cell arrayed as homodimers and homotetramers.[416a] The protein has a typical transport channel structure with 12 membrane spanning domains and a large hydrophilic cytoplasmic loop in the center.[417] In humans, Glut1 transports dehydroascorbic acid (DHA, the oxidized form of vitamin C) as well as glucose.[418,418a] Remarkably, Glut1 is only expressed in the mature red cells of a small subset of mammals that have lost the ability to synthesize ascorbic acid from glucose, including humans, some of the other higher primates, guinea pigs, and fruit bats.[413] In other mammals, Glut1 is expressed in fetal red cells but is lost soon after birth.[419] In mice, Glut4 synthesis is upregulated as Glut1 disappears and presumably takes over the job of supplying the glucose needed to fuel the red cell. The change from transport of glucose to transport of DHA in humans is tied to the binding of stomatin to Glut1.[413] Under physiologic conditions adequate glucose is transported because the concentration of glucose in the plasma (~5 mM) greatly exceeds the concentration of DHA (<2 μM). This may not be so in the leakiest hereditary stomatocytes where the cells need prodigious amounts of ATP to pump out a torrent of Na^+ and water and survive (see Chapter 16).

Glut1 also interacts with dematin and adducin (see Fig. 15-6)[420] and perhaps band 3 (unpublished comment[421]). These interactions contribute to connecting the membrane skeleton to the lipid bilayer. It will be interesting to see whether they also regulate the function of Glut1.

MEMBRANE SKELETON PROTEINS

Spectrin

Erythroid spectrin is the major constituent of the red cell skeleton, accounting for 50% to 75% of the skeletal mass.[166,167] Its discovery by Marchesi and Steers in 1968 launched the modern era of investigation of the plasma membrane.[422] The spectrin-based skeleton is anchored to the plasma membrane by an ankyrin-mediated linkage to band 3 and its associated proteins at one end of spectrin[423] and by a protein 4.1R–mediated attachment to band 3 and glycophorin C and other proteins in another multiprotein complex at the opposite end of spectrin (see Fig. 15-6). Spectrin is composed of two large polypeptide chains: a 280-kD α chain and the 246-kD β chain that are structurally similar but functionally distinct (Fig. 15-13, *A*). The two chains associate side by side in an opposing (antiparallel) orientation[424] and are twisted about each other in a right-handed double helix.[425]

The Spectrin Family in Humans is Encoded by at Least Seven Distinct Genes. Two genes encoding for α spectrin and five genes encoding for β spectrin have been characterized.[426] The αI-spectrin gene *(SPTA)* is located on chromosome 1q22-q23 adjacent to the Duffy blood group and encodes the erythroid-spectrin α chain.[427] The αII-spectrin (also called α-fodrin) gene *(SPTAN1)* encodes an α-spectrin homologue found in nearly all cells except mature red cells.[428] The βI-spectrin gene *(SPTB)* is located on chromosome 14q23-q24.2 and encodes the β subunit of erythroid spectrin,[429] designated βI, isoform 1 (or βIΣ1). The βI gene promoter region contains specific GATA1 and CACCC-related protein binding sites that account for specific, high-level expression in erythroid cells.[430] Differential 3′-processing of the βI-spectrin pre-mRNA generates an alternative, longer βI-spectrin subunit (βI, isoform 2 or βIΣ2) that is found in brain and muscle.[431] The βII-spectrin (also called β-fodrin) gene *(SPTBN1)* encodes the generally expressed β subunit of spectrin, which shares 60% amino acid identity with βI spectrin.[432] Thus erythrocyte spectrin is composed of αI and βI (isoform 1) chains and the widely expressed spectrin (called fodrin, tissue spectrin or brain spectrin) contains αII and βII subunits. Muscle spectrin is believed to contain predominantly αII and βI (isoform 2) subunits.

βIII and βIV spectrins are predominantly expressed in the central nervous system. Gene mutations cause neurologic diseases.[433-435] A truncated isoform of βIV spectrin is associated with a subnuclear structure (promyelocytic leukemia bodies) and may be part of a nuclear scaffold.[436] βV spectrin is mostly in retinal rods and cones and in gastric epithelial cells.[437] Other spectrin-related proteins—dystrophin, utrophin, actinins, plakins, and dystonin among others—are not relevant to red blood cells.

Spectrin Repeats

Spectrins Consist Mostly of Tandem 106-Amino Acid Repeats. Each spectrin chain is composed of a series of approximately 106-amino acid repeats. Each repeat is formed by three α-helices that are folded into a triple helical bundle.[438-440] The α and β spectrins contain 20 and 16 full repeats, respectively.[427,429] An SH3 domain within the α chain is conventionally called repeat α10, although it is not a true spectrin repeat (see Fig. 15-13, *A*). As will be discussed, the α0 and β17 repeats are complementary partial repeats that join to form a full repeat and link spectrins together. The primary sequence of each repeat

Figure 15-13 Spectrin structure. **A,** Overall organization. The α and β chains are aligned antiparallel with respect to their N- and C-terminal ends. The approximately 106-amino acid "spectrin repeats" are numbered from the N-terminal of each chain. Each repeat is composed of three α helices (A, B, and C). The SH3 domain, which extrudes from between helix B and helix C of repeat 9, is conventionally numbered as a repeat 10, although it is not a spectrin repeat. Similarly, by convention the partial spectrin repeat that begins the α-spectrin chain is called α0, whereas the partial spectrin repeat at the end of the β-spectrin chain is called β17. Note that the spectrin self-association site is formed by joining these two complementary partial repeats (α0 and β17) at the "head" ends of the two chains *(inset)*. The α chain contributes helix C and the β chain helices A and B. Some repeats are specialized, such as β14-β15, which forms the ankyrin-binding site; α4, where the Lu blood group glycoprotein attaches; the several repeats marked "PS," which bind phosphatidylserine; and parts of the first four repeats at the "tail" of each chain, which nucleate interchain, heterodimer interactions. Repeats marked with a *blue star* are relatively unstable at physiologic temperatures and may unfold when spectrin is deformed, increasing flexibility. *Rectangles* denote peptide segments that differ from the repeats and the SH3 domain. They include the actin/protein 4.1/adducin-binding sites and a calmodulin-like Ca^{2+}-binding region (EF hands) that also binds protein 4.2. The structures of these two domains are shown in more detail in the *insets*. **B,** Space-filling model of the spectrin heterotetramer at the self-association site. One α chain is *red*, the other is *tan*. The β chains are *light blue*. **C,** Spectrin-ankyrin interaction. Note how ZU5-ANK, the spectrin-binding subdomain within ankyrin, binds in the notch created by the sharp angle between spectrin repeats β14 and β15. The primary contacts are with helix C of repeat 14 and the loop between helices B and C of repeat 15. *(B, from Li D, Harper SL, Tang HY, et al: A comprehensive model of the spectrin divalent tetramer binding region deduced using homology modeling and chemical cross-linking of a mini-spectrin.* J Biol Chem *285:29535–29545, 2010; C, from Ipsaro JJ, Mondragón A: Structural basis for spectrin recognition by ankyrin.* Blood *115:4093–4101, 2010.)*

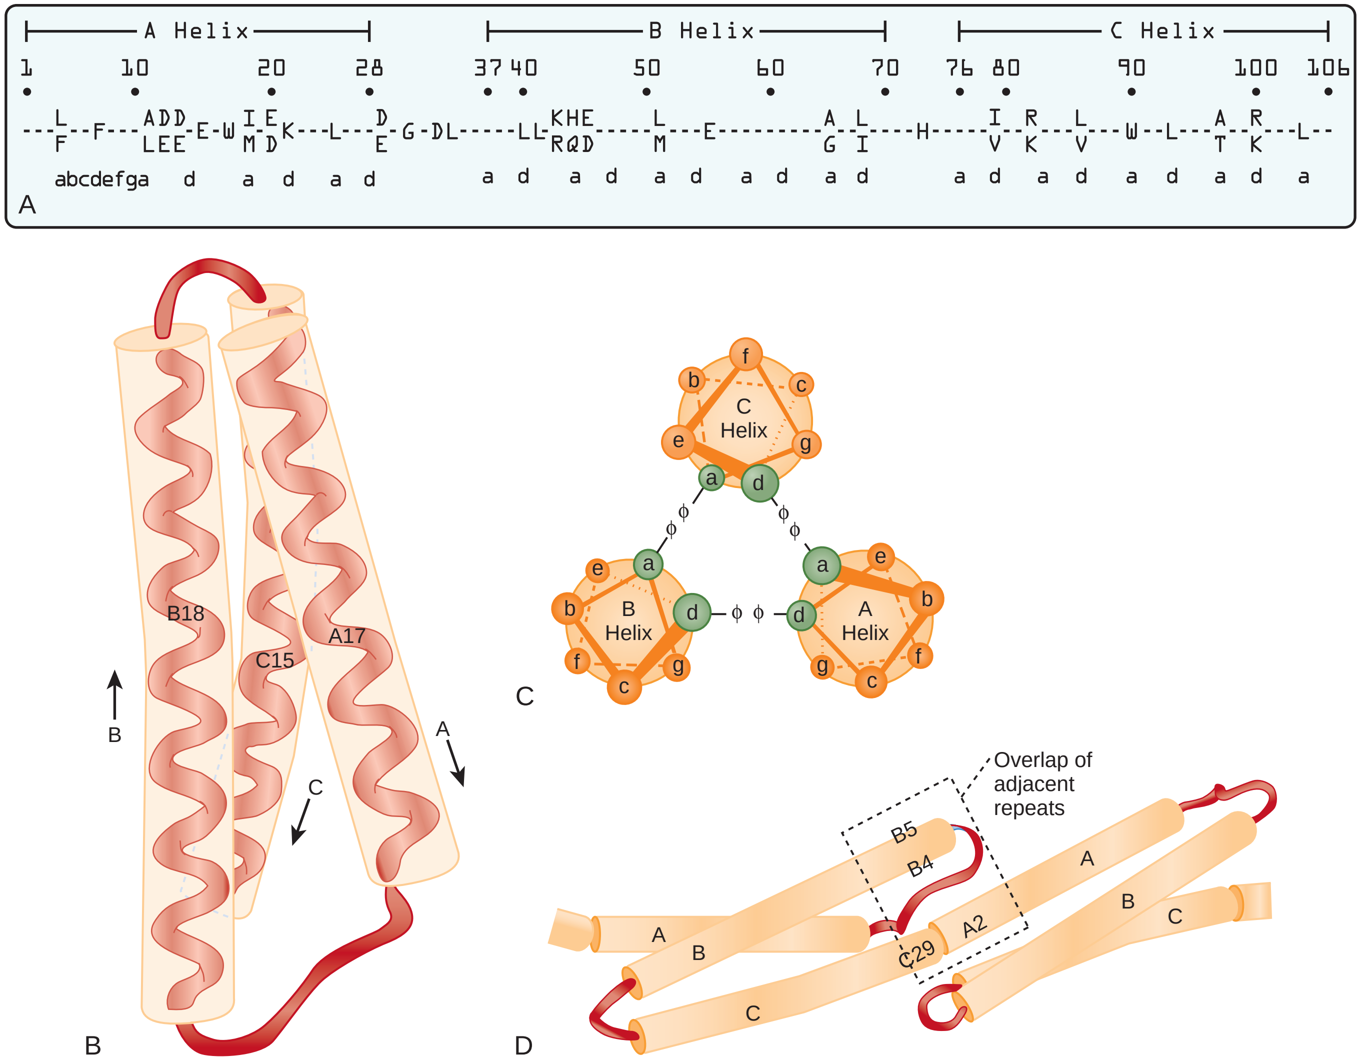

Figure 15-14 Structure of spectrin repeats. **A,** Consensus sequence of a typical 106-amino acid, human erythrocyte spectrin repeat phased according to crystallographic data, which identifies three α helices per repeat. Less-conserved amino acids are marked with a *dash*. The amino acids in the repeat are designated “a” through “g.” The distance from one “a” to the next corresponds to two turns of the α helix. Residues “a” and “d” are the major contact points between helices. They tend to be hydrophobic and are conserved in most spectrins. **B,** Model of a single typical repeat. The positions of the nearly invariant tryptophans at A17 (Trp at amino acid 17 of the repeat) and at C15 (Trp at position 90) are shown. They interact with surrounding residues, including B18 (repeat amino acid 54), at the central junction where the A helix crosses over from B to C. **C,** Cross-section of a typical repeat. Note that the A, B, and C helices are in a triangular array and that the “a” and “d” residues lie on one face of each helix. The side chains of these amino acids are usually hydrophobic (Φ) and interact with each other to stabilize the triple helical configuration. Salt bonds between the typically polar amino acids at positions “e” and “g” also help attach the BC and AC helices to each other. **D,** Interconnection of two adjacent repeats. The A and C helices are colinear, forming one long helix. The distal repeat of each pair is rotated 60 degrees (right-handed). Note that the B helix of the proximal repeat overlaps the A helix of the following repeat. Interactions in the overlap region among conserved hydrophobic residues, such as C29, B4, and B5 (repeat amino acids 104, 40, and 41, respectively), and the mostly hydrophobic residues at A2 (repeat amino acid 2) probably stabilize the connection and limit mobility at the repeat junction.

exhibits extensive heptad (seven-residue) symmetry, with conserved hydrophobic residues situated in the first and fourth positions of each heptad motif (designated as positions *a* and *d* in Fig. 15-14, *A*).[438,440] Each triple helical spectrin repeat is approximately 5 nm long and 2 nm wide (see Fig. 15-14, *B*) and is rotated 60 degrees (right-handed) relative to the neighboring repeats.[440] Details of the structure are presented in Figure 15-14 and in catalogs of spectrin repeat structures.[441]

Although spectrin is often depicted as a highly flexible molecule, the repeats themselves appear rigid and the crystal structures of multiple repeats do not show significant flexibility at the junction between repeats (see Fig. 15-14, *D*). However, the stability of individual repeats varies and some are unstable at physiologic temperatures, which would introduce flexibility.[442] Two of the less stably folded repeats, α13-α14 and β8-β9, are adjacent to each other in the spectrin molecule (see Fig. 15-13, *A*) and may form a hinge.[443,444] Measurements of the force required to unfold a spectrin repeat show that the repeats function as elastic springs.[445] When intact red cells deform, certain spectrin repeats partially unfold, which presumably contributes to the elasticity.[446]

Spectrin Heterodimerization

Side-to-Side Interactions Between α and β Chains Results in Zipperlike Dimerization. Nucleation sites located at repeats 18 to 21 of the α chain and 1 to 4 of the β chain are implicated in triggering the zipping up of α and β chains (see Fig. 15-13, *A*).[447] The key interactions are between the A and B helices of β spectrin repeat 1 and the C and A helices of α spectrin repeat 21 and between the C and A helices of β2 and the A and B helices of α20.[448] These helices form complementary charged surfaces that draw the two chains together.[449] After the initial tight association of these nucleation sites, a conformational change is propagated, causing the remainder of the α and β chains to pair together.[450] The two chains twist around each other with a periodicity of a complete turn approximately every four[425] to eight[450] repeats. The side-to-side interactions beyond the nucleation site are relatively weak,[451] which may be important in allowing the α and β chains to slide past each other when the spectrin molecule flexes in the plane of the membrane. A common polymorphism of the α-spectrin allele, α^{LELY}, encodes α chains that lack one of the nucleation sites and therefore do not form stable heterodimers.[452,453] This clinically relevant allele is discussed in under "Hereditary Elliptocytosis" in Chapter 16.

Spectrin Self-Association

Spectrin Tetramerization Occurs in Head-to-Head Fashion by Association of the Partial Repeats at the Ends of α- and β Spectrin and Side-to-Side Association of the First Three α-Spectrin Repeats.[454,455] The "self-association" sequences required for tetramerization are located at the N-terminus of the α-spectrin chain and the C-terminus of the β-spectrin chain. This is called the "head" end of spectrin and is opposite the "tail" end where binding to actin occurs and where the nucleation site is found (see Fig. 15-13, *A*). The specific structure of the spectrin self-association site has been extensively analyzed.[450,456,457] The free C helix at the N-terminus of α spectrin (α0) associates with the free A and B helices at the C-terminus of β spectrin (β17) to form a stable triple helical bundle repeat (α0/β17). In this manner, spectrin heterodimers associate to form tetramers and higher-order oligomers in head-to-head fashion (see Fig. 15-13, *A*).

In isolated spectrin heterodimers the partial repeats at the ends of the α and β chains are bound to each other. The longer α chain folds back on itself so that the noncovalent α0/β17 repeat lines up and interacts with repeat α4 and so that repeats α3 and α1 interact with each other. In the heterotetramers, there are three such side-to-side interactions between repeats in the two α-spectrins (α and α′): α1-α′3, α2-α′2, and α3-α′1 (see Fig. 15-13, *B*). These additional lateral interactions, although weak, contribute to self-association.[450,457] For dimers to associate into tetramers or vice versa, the bonds involved in self-association must first open. This is the rate-limiting step in dimer-to-tetramer interconversion.[458]

The formation of spectrin tetramers and higher-order oligomers is critical to maintaining the mechanical strength of the membrane skeleton.[459] Mutations in α or β spectrin that interfere with self-association[456] weaken the membrane skeleton. Such defects are by far the most common cause of hereditary elliptocytosis and hereditary pyropoikilocytosis (see Chapter 16).

Spectrin Exists Predominantly as Tetramers in Vivo.[460] Physiologic ionic strength and lower temperatures (25°C) favor tetramer formation; low ionic strength and physiologic temperatures favor dissociation to dimers.[459,461] The self-association of spectrin can be studied in purified spectrin and by manipulating red cell ghosts to alter the degree of spectrin oligomerization.[454,459,461,462] In red cell ghosts, driving the equilibrium toward dimerization produces exceedingly fragile structures, underscoring the importance of spectrin tetramerization in membrane skeletal stability.[459] At 4°C, the dimer-tetramer equilibrium is nearly kinetically frozen owing to its high activation energy.[454] Thus spectrin eluted from ghosts at that temperature retains the degree of oligomerization that existed in vivo. In such eluates, approximately 5% of the spectrin is heterodimers, approximately 50% exists as heterotetramers, and the remainder are divided among higher-order spectrin oligomers and high-molecular-weight complexes of spectrin, actin, protein 4.1R, and dematin.[460]

Spectrin Structure In Situ

Spectrin Molecules are Condensed in Vivo. Electron micrographs of purified spectrin tetramers[455,463] or spectrin filaments in fully stretched skeletons[464] show the molecule has an end-to-end length of 200 nm. But, as discussed later, simple calculations show that spectrin tetramers can only have a length of 62 to 72 nm in vivo. This correlates with the observed length of spectrin filaments in unstretched and partially stretched skeletons.[425] It is not known exactly how spectrin is folded in this physiologic filament. The best morphologic evidence is that the α and β subunits form a double helix and are twisted about each other along a relatively straight common axis (Fig. 15-15).[425] Spectrin molecules extend and contract along this axis by varying the pitch and diameter of the double strand. This springlike behavior serves as a "molecular shock absorber"[465] and is presumably critical to the elastic behavior of the membrane. Native spectrin tetramer has approximately 10 turns with a pitch of 7 nm and a diameter of 5.9 nm.[425] This corresponds to 1 turn every four spectrin repeats. Structural analyses of the spectrin self-association site also show that the chains coil around each other, but with a periodicity of about 1 turn per eight repeats (see Fig. 15-13, *B*).[450] Other structural models suggest there is some bending between spectrin repeats or that helices within some repeats may "melt" and rearrange, shortening the repeat.[466] Whatever the mechanism, it is clear that the ends of a spectrin molecule are normally only about one-third as far apart as they appear in stretched skeletons.

Spectrin Interactions

Spectrin Contains Important Functional Domains Involved in Protein-Protein Interactions. In addition to

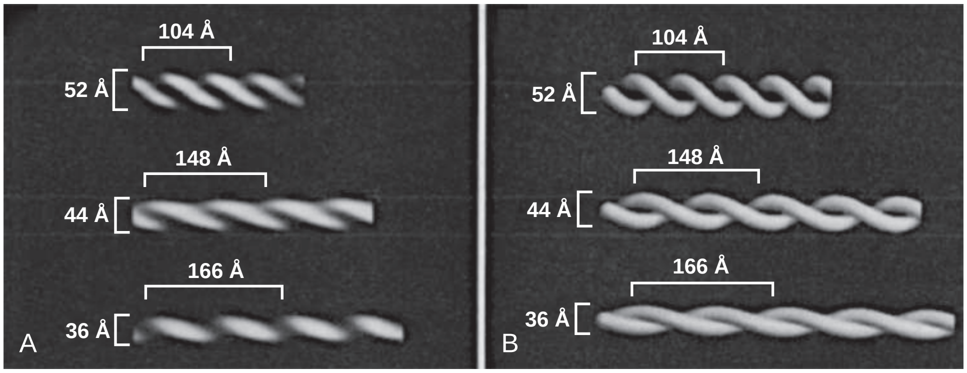

Figure 15-15 Model of spectrin structure in situ on the membrane. **A,** Enhanced images of spectrin molecules captured from negatively stained electron micrographs of variably expanded membrane skeletons. In general, spectrin molecules were relatively straight but of variable lengths and on image enhancement showed a coiled appearance. **B,** Right-handed double helical model derived from the images in **A**. The pitch of the helix varies from 10.4 nm (1 nm = 10Å) to 16.6 nm in the images shown, and the diameter varies from 5.2 nm to 3.6 nm. Like a spring, as spectrin extends, the pitch of the helix lengthens and the diameter narrows. The average pitch and diameter in unstretched skeletons are calculated to be 7 nm and 5.9 nm, respectively. This corresponds to about five turns per spectrin dimer and four repeats per turn for a length of 35 nm per spectrin dimer. This is far less than the length of full extended spectrin dimers (100 nm) and almost exactly to the length of spectrin dimers from calculations based on the number of actin junctions (40,000 in a red cell surface of 140 μm^2) and from direct measurements in unstretched skeletons. *(From McGough AM, Josephs R: On the structure of erythrocyte spectrin in partially expanded membrane skeletons.* Proc Natl Acad Sci U S A *87:5208-5212, 1990.)*

the critical sequences involved in spectrin nucleation and self-association, the α and β chains interface with other proteins, including ankyrin, proteins 4.1R and 4.2, actin, adducin, and dematin, via defined structural domains (see Fig. 15-13, *A*).

Ankyrin-Binding Site. Repeats 14 and 15 of β spectrin are crucial for ankyrin binding, especially the C helix of repeat β14 and the loop between helices B and C of repeat β15.[467-469] Repeat β15 forms an unusual angle with repeat β14, and the spectrin-binding region of ankyrin (called ZU5A or ZU5-ANK, discussed under "Ankyrin") nestles into the corner formed by the two repeats (see Fig. 15-13, *C*).[469] The attachment of β spectrin to ankyrin and ankyrin to band 3 and some of its associated proteins (see Fig. 15-6) creates spectrin's strongest link to the overlying lipid bilayer. In nonerythroid cells, ankyrin homologues mediate the linkage of spectrin to many other proteins of the plasma membrane, including Na$^+$,K$^+$-ATPase[470] and voltage-dependent sodium channels.[471]

Binding Sites for F-Actin, Protein 4.1R, Adducin, and Dematin. The N-terminal 301 amino acid of β spectrin binds protein 4.1R[472,473] and actin[463,473,474] and shares sequence homology with several actin-binding proteins, including calponin, α actinin, dystrophin, filamin, ABP 120, adducin, and fimbrin. There are two of these "calponin homology domains" (CH1 and CH2) in tandem in β spectrin. It appears that protein 4.1R and actin bind to each of these domains.[473] Binding to CH2, the more C-terminal CH domain, is normally inhibited by an α helix at its N-terminus, which may serve a regulatory role (see Fig. 15-13, *A*). PIP$_2$ increases attachment of protein 4.1R to the CH domains.[473]

Adducin binds to the N-terminal actin-binding domain and the first two repeats of β spectrin.[475] Because mutations within the last few repeats of α spectrin markedly reduce membrane adducin content,[476] the C-terminus of α spectrin probably also contributes to adducin binding.

Dematin, but not phosphorylated dematin, binds somewhere in the tail region of spectrin and facilitates binding of spectrin to F-actin. The exact binding site is unknown.[477]

The tail ends of spectrin tetramers and oligomers bind to short, double-helical protofilaments of F-actin. The interaction is greatly enhanced by protein 4.1R.[478-480] Approximately six spectrins can be accommodated on each actin protofilament, leading to the characteristic quasi-hexagonal organization of the membrane skeleton (Fig. 15-16). The spectrin/actin/protein 4.1R junctional complexes contain other proteins, including adducin, dematin, tropomyosin, tropomodulin, and p55. These are discussed in the sections that follow.

EF Hands: Ca^{2+}- and Protein 4.2–Binding Sites and Role in Spectrin-Actin Binding. The C-terminus of α spectrin, like α actinin, contains two pairs of EF hands (see Fig. 15-13), which are structures that bind and mediate the regulatory effects of calcium.[481,482] The N-terminal EF hands (EF$_{1,2}$) are structurally similar to calmodulin[483] and bind Ca^{2+} with low affinity. Ca^{2+} binding to EF$_1$ triggers a conformational change that allows EF$_2$ to bind Ca^{2+}.[484] The C-terminal EF hands (EF$_{3,4}$) are Ca^{2+} insensitive and similar to those in α actinin.[485]

The EF hand domain binds protein 4.2 with high affinity (kD = 3 ×10^{-7} M).[486] The binding capacity is augmented by micromolar concentrations of Ca^{2+}, and the Ca^{2+} effect is blocked by calmodulin, which also binds to the domain. Because protein 4.2 binds to band 3, this adds to the evidence that a portion of band 3 is located near the spectrin-actin junctions and serves as a secondary site for attaching the membrane skeleton to the lipid bilayer. It is not known whether protein 4.2 actually binds to the EF hands in vivo and, if so, what fraction of the protein is located there and what fraction is located in the ankyrin complex (see Fig. 15-6).

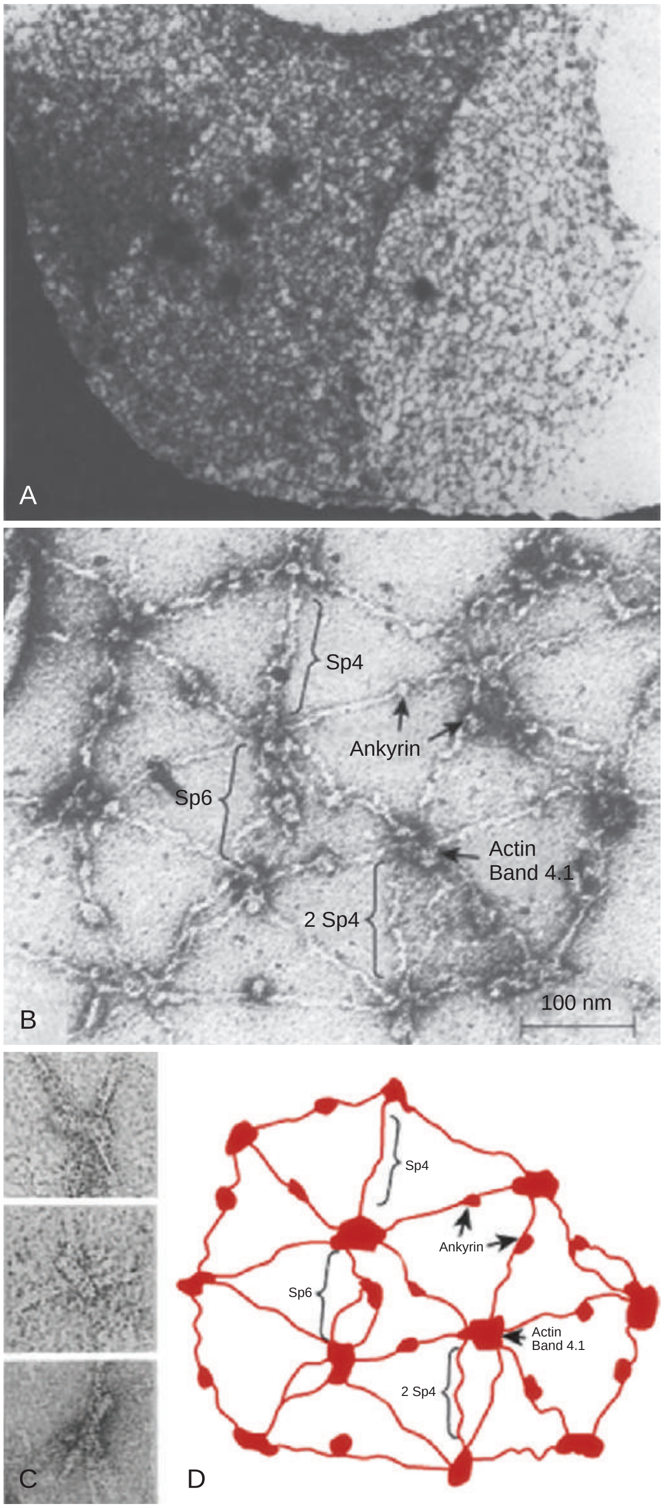

Figure 15-16 Negatively stained electron micrographs of red cell membrane skeletons that have been stretched during preparation to reveal details of their structure. **A,** Low magnification to emphasize the ordered, netlike structure. **B,** High-magnification view and schematic showing the predominantly hexagonal organization of the skeleton. **C,** Detail of the 37-nm long F-actin protofilaments. **D,** Location of various skeletal elements is shown in **B.** *Sp4,* spectrin tetramer; *Sp6,* spectrin hexamer. *(From Palek J, Sahr KE: Mutations of the red blood cell membrane proteins: from clinical evaluation to detection of the underlying genetic defect.* Blood *80:308, 1992; and Byers T, Branton D: Visualization of the protein associations in the erythrocyte membrane skeleton.* Proc Natl Acad Sci U S A *82:6153, 1985.)*

The relationships of the EF hand domain, the calponin homology domain, and F-actin are not known in spectrin but are likely to resemble those in α actinin (Fig. 15-17).[487,488,489] That is, the EF hands probably abut the actin/protein 4.1R–binding CH domains and may help regulate actin binding. Previously the EF hands were believed to be impotent in erythroid spectrin, although they were known to bind Ca^{2+} and affect the function of αIIβII spectrin (fodrin).[481] However, deletion of just the C-terminal 13 amino acids in the EF domain of the sph^{1J} mouse leads to a severe, spherocytic hemolytic anemia and failure of the mutant spectrin to assemble into the membrane skeleton.[490] Also, PfEMP3, a protein from *P. falciparum* that appears on the red cell membrane late in the parasite life cycle, binds to α spectrin in the EF hand domain region and disrupts the spectrin/actin/protein 4.1R complex, perhaps as a precursor to release of new parasites into the circulation.[488] These observations show that the EF hand domain is functionally important, and direct evidence supports this conclusion. A minispectrin composed of the actin binding and EF hand domains and the four adjacent spectrin repeats in each chain that form the nucleation site binds to F-actin with the aid of protein 4.1R, as expected, but this binding is blocked if the EF hands are missing, or even if just the last 13 amino acids of α spectrin are deleted, as in the sph^{1J} mouse.[489]

SH3 Domain. The tenth "repeat" of α spectrin encodes an *src* homology (SH3) domain. SH3 domains generally function as sites of protein-protein attachment at cell membranes. The function of the erythroid α-spectrin SH3 domain and the protein(s) that bind to it in the red cell are not known. One candidate belongs to a

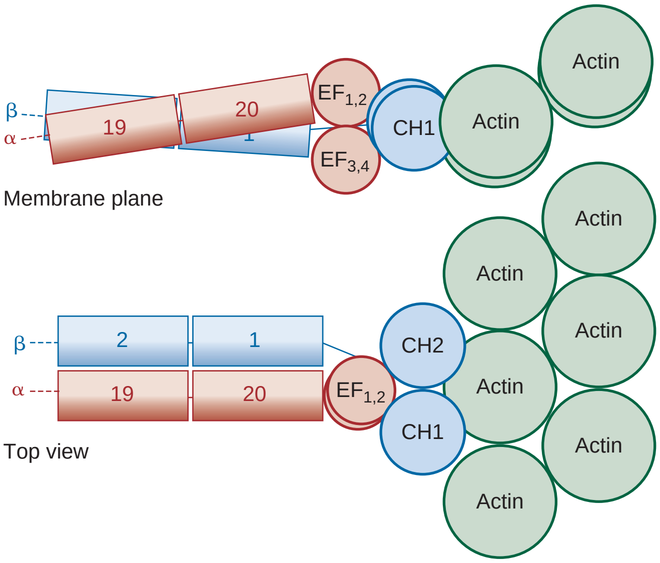

Figure 15-17 Structural model, roughly to scale, of the tail end of spectrin deduced from the structure of α actinin.[487] *Top,* View from within the plane of the membrane skeleton. *Bottom,* View looking down on the membrane. CH1 and CH2 are the actin- and protein 4.1R–binding sites in the N-terminal, actin-binding domain of β spectrin. $EF_{1,2}$ and $EF_{3,4}$ are the N-terminal and C-terminal pairs of EF hands, respectively, in the EF domain, which lies at the C-terminal end of α spectrin. The intimate relationship between the EF and CH domains and recent evidence that the EF domain is required for optimal spectrin-actin binding[488,489] suggest the EF hands may regulate actin binding.

family of tyrosine kinase–binding proteins.[491] Interestingly, plasmepsin II, the aspartic protease of *P. falciparum,* cleaves spectrin mainly within the SH3 domain of α spectrin, suggesting that specific targeting of the SH3 domain by *P. falciparum* may be part of the strategy to dismantle the membrane skeleton.[492]

PH Domain. All β spectrins *except* the major erythroid isoform (βI, isoform 1) have a C-terminal extension that contains a pleckstrin homology (PH) domain.[493,494] The specialized 100-residue PH domain is believed to mediate membrane targeting of proteins.[494,495] The muscle isoform of erythroid spectrin (βI, isoform 2) contains a PH domain,[431] and mature red cells contain a small amount of this isoform, which is clumped in submicron-size patches within the membrane skeleton.[496] The erythroid spectrin PH domain binds with equal affinity to PIP_2 and phosphatidylinositol-3,4,5-trisphosphate (PIP_3).[497,498] The function of the PH domain in red cells is untested. Perhaps it contributes to the attachment of spectrin to the membrane.

Phospholipid Binding. In addition to the PH domain, which binds phosphatidylinositols (PI), other parts of spectrin also bind phospholipids. Several spectrin repeats in each chain bind phosphatidylserine (PS)[89] (Fig. 15-13, *A*). The PS binding sites on β spectrin are located near the site where ankyrin and the junctional complex bind, leading to speculation that PS influences these interactions.[89] Whatever the mechanism, the PS-spectrin interaction increases membrane stability[90] and protects spectrin from glycation.[91]

The β14-β15 spectrin repeats, which form the ankyrin binding site, also bind phosphatidylcholine (PC) and phosphatidylethanolamine (PE).[498a] Spectrin-PE/PC binding is inhibited by ankyrin.[498a] The importance of this is unclear, though it may partly explain how a normal membrane skeleton can form in red cells lacking ankyrin[498b] or band 3.[220] The topic of spectrin-lipid binding was recently reviewed.[498c]

Phosphorylation Sites. Instead of a PH domain, the C-terminal region of erythrocyte (βI, isoform 1) spectrin contains a 52-amino acid extension just beyond the site of self-association that is phosphorylated by a membrane-associated casein kinase-I (see Fig. 15-13).[499] There are five serines and one threonine that are phosphorylated in a sequential fashion.[500] In vitro phosphorylation of β spectrin has no effect on spectrin self-association.[454,501,502] However, by some unknown mechanism, increased phosphorylation of β spectrin in vivo decreases membrane mechanical stability whereas decreased phosphorylation strengthens the membrane.[503]

Ubiquitination Sites. α-Spectrin is ubiquitinated at several sites in the C-terminal region.[504,505] The consequences are uncertain. There is evidence from one group that spectrin contains ubiquitin-conjugating (E2) and ligase (E3) activities,[505] that ankyrin is also ubiqitinatinated,[506] and that ubiquitination favors loss of spectrin from the actin junctional compex,[507] but these observations have not yet been confirmed. The fraction of spectrin molecules that is ubiquitinated in vivo is not clear, and the effect of ubiquitination on the mechanical properties of the intact red cell is not known.

Tryptic Domains. The tryptic domains of spectrin have important historical, structural, and clinical significance. Gentle proteolysis of spectrin with trypsin generates nine structural domains, each composed of several 106-amino acid repeats.[424,508] Five tryptic fragments represent most of the α chain and include the αI (80-kD), αII (46-kD), αIII (52-kD), αIV (52-kD), and αV (41-kD) domains; the β chain is digested into four domains, including βI (17-kD), βII (65-kD), βIII (33-kD), and βIV (74-kD). Many of the molecular defects in hereditary elliptocytosis were initially identified as abnormalities in spectrin domain maps after proteolytic digestion (see “Hereditary Elliptocytosis” in Chapter 16), and many older articles refer to these domains.

Mutations in Erythroid Spectrin Affect the Integrity of the Red Cell and Lead to Clinical Disease

Defects that impair spectrin self-association are the major cause of hereditary elliptocytosis, and spectrin deficiency is an important cause of hereditary spherocytosis (see “Hereditary Elliptocytosis” and “Hereditary Spherocytosis” in Chapter 16).

Actin

The red cell contains β actin, which is the actin subtype found in a wide variety of nonmuscle cells.[134] Whereas red cell actin shares structural and functional similarities with the β actin found in nonerythroid cells, in the membrane skeleton actin is assembled into 30,000 to 40,000 regular *protofilaments* or short, 33- to 37-nm, double-helical F-actin filaments, each containing about 14 monomers.[134,509,510] In contrast to nonerythroid cells, where actin filaments have variable lengths and turnover rapidly, red cell actin protofilaments are a constant size and are extraordinarily stable, persisting for the life of the red cell. They are stabilized by (1) interactions with spectrin, protein 4.1R, and tropomyosin; (2) capping of the pointed or slow-growing end by tropomodulin[511]; and (3) capping of the barbed or fast-growing end by adducin.[512] This is another unique feature of the actin filaments in red cells because capZ is the ubiquitous barbed-end capping protein in nonerythroid cells.[513] Interestingly, this occurs despite the fact that red cells contain capZ.[513] When α or β adducin is deleted in red cells, capZ expression is greatly upregulated, presumably as a compensatory mechanism.[223,514]

The actin protofilaments function as junctional centers connected by spectrin in a more or less hexagonal array (see Fig. 15-16).[464,510] The protofilaments lie parallel to the lipid bilayer within 20 degrees of the membrane plane.[515] Spectrin dimers bind to the side of actin filaments at a site near the tail of the spectrin molecule (see Figs. 15-13 and 15-17).[463] The contact sites of spectrin on the actin protofilaments are not known, although one can make inferences from the way other spectrin-related proteins bind F-actin (see Fig. 15-17). Spectrin tetramers are bivalent and therefore cross-link actin filaments, although binding is weak (kD ~ 10^{-3} M) and ineffectual in the absence of protein 4.1R.[479] Spectrin-actin interactions are specifically enhanced by protein 4.1R, adducin, and dematin (see “Protein 4.1R,” “Adducin,” and “Dematin”).

Defects in Actin Assembly. Not much is known about how the unique actin protofilaments of red cells are assembled, but some hints are emerging from defects in actin assembly. Red cells contain multiple members of the Rho family of guanosine triphosphatases (GTPases), including Rac1, Rac2, Cdc42, and RhoA, RhoG, and RhoH.[516] Rac GTPases are activated by extracellular signals via guanine nucleotide exchange factors, which replace guanosine diphosphate (GDP) with GTP on Rac. GTP-activated Rac then interacts with P21-activated kinase, a diaphanous homologue (DIAPH3), and an assembly of proteins known as the Wiskott-Aldrich syndrome verprolin-homologous protein (WAVE) complex,[517] stimulating ARP2/3 to initiate actin polymerization in many cell types.[518] Erythrocytes probably also utilize this pathway because they contain Rac, RhoA, and all the members of the WAVE complex.[519-521]

Mice that lack both Rac1 and Rac2 develop a microcytic hemolytic anemia with marked anisocytosis and poikilocytosis.[520] Membrane skeletal junctions are aggregated, and there is pronounced irregularity of the spectrin meshwork. These changes are accompanied by decreased cellular deformability, an increase in the actin-to-spectrin ratio, and increased phosphorylation (Ser724) of adducin, an F-actin capping protein. Actin and phosphorylated adducin are more easily extracted by Triton X-100 from Rac1(−/−)/Rac2(−/−) red cells, indicating weaker association to the cytoskeleton.

Hematopoietic protein-1 (Hem-1) is a hematopoietic cell specific member of the WAVE complex. Mice lacking Hem-1 resemble the Rac1/Rac2 double knockout mice, with a moderate microcytic, hemolytic anemia, marked spherocytosis and poikilocytosis, clumped F-actin filaments, and decreased amounts of all membrane skeletal proteins.[521] They also show increased expression of Ser724 on adducin.

Osteopontin phosphorylates or activates multiple proteins in human erythroblasts, including Rac-1 GTPase and adducin. Osteopontin knockout mice are anemic and also show defects in F-actin filaments.[522]

The results indicate that Rac GTPases regulate the organization of the red cell membrane skeleton. It is unclear whether this occurs dynamically in the mature red cell or just during erythropoiesis.

Malaria. *P. falciparum* generates a host-derived actin cytoskeleton within the red cell that appears to be an extension of the normal membrane skeleton. It functions in the transport of vesicles between the parasite and the red cell membrane. This cytoskeleton is abnormal in erythrocytes containing hemoglobins S or C, two hemoglobins that protect against malaria.[523] One possible mechanism is that hemoglobin oxidation products, which are enriched in hemoglobin S and C red cells, inhibit actin polymerization in vitro.

Protein 4.1R

Red cell protein 4.1 (technically the 4.1R paralogue, gene name *EPB41*) is a major component of the erythrocyte membrane skeleton, with roughly 200,000 copies present in each red cell (see Table 15-2). Protein 4.1R confers both stability and flexibility to circulating red cells by potentiating the interaction of spectrin tetramers with F-actin[479,524] and by linking this membrane skeletal scaffold to the plasma membrane through vertical interactions with GPC, band 3, p55, protein 4.2, and perhaps other proteins (see Fig. 15-6). In the mature red cell, protein 4.1R exists as a 588-amino acid protein that has a molecular weight of 66 kD, although it runs as an 80-kD protein on SDS gels. Two forms of the protein are resolved on high-resolution SDS gels, an apparently 80-kD protein designated 4.1Ra and an apparently 78-kD protein designated 4.1Rb. Protein 4.1Ra derives from 4.1Rb by progressive deamidation of Asn502 during the life span of the red cell; thus protein 4.1Ra is more prominent in senescent red cells.[525] Proteolysis of protein 4.1R generates four structural domains: the N-terminal 30-kD membrane binding domain (MBD; also called the FERM domain[526]), a 16-kD linker domain, the 10-kD spectrin-actin–binding domain, and the 22- to 24-kD C-terminal domain (Fig. 15-18).[527]

Spectrin-Actin–Binding Domain

Protein 4.1R Significantly Enhances the Interaction of Spectrin with Actin. In physiologic solvent conditions, spectrin tetramers bind weakly to F-actin (kD ~ 10^{-3} M), whereas the addition of protein 4.1R generates a high-affinity ternary complex (kD ~ 10^{-12} M^2).[479] The 10-kD domain of 4.1R specifically facilitates spectrin-actin interactions[524] and is encoded by alternatively spliced exon 16 and constitutive exon 17.[528,529] A 21-amino acid peptide encoded by exon 16 plus seven amino acids (amino acids 37 to 43) from exon 17 form the spectrin-binding site.[528,529] Protein 4.1R binds to F-actin as well as spectrin.[528,530] The stoichiometry of protein 4.1R/actin binding is 1:1, and the interaction is highly cooperative, such that binding of one protein 4.1R molecule induces a conformational change in the actin protofilament that promotes further protein 4.1R binding.[529,530] The binding site is located within the first 26 amino acids of exon 17, particularly a critical 8-amino acid sequence (LKKNFMES).[528,531] Thus the actin site is straddled by the bipartite spectrin binding site.[528,531] The available data suggest that protein 4.1R facilitates spectrin-actin binding by bridging spectrin and actin in a strong ternary complex.

The critical role of protein 4.1R in maintaining red cell membrane stability is underscored by the erythrocyte membrane fragility and resultant severe hemolysis observed in patients who lack protein 4.1R (see "Hereditary Elliptocytosis" in Chapter 16). Interestingly, normal membrane stability is completely restored when patient red cell ghosts are reconstituted with a 64-amino acid fusion protein containing the spectrin-actin–binding site.[529] This finding highlights the critical functional role of the 10-kD domain of protein 4.1R in red cell function.

Membrane-Binding Domain or FERM Domain

The protein 4.1 paralogues are part of an interesting group of proteins known as FERM proteins.[526,532] These include the four protein 4.1 proteins, plus ezrin, radixin,

moesin, and others. Despite their diverse functions, the FERM proteins each utilize the conserved 30-kD MBD, or FERM domain, to facilitate interactions with cellular membranes.

Protein 4.1R Links the Membrane Skeleton to the Plasma Membrane Through Interactions with the Integral Membrane Proteins GPC and GPD (GPC/D). The majority of membrane-associated protein 4.1R is bound to the C-terminus of GPC/D via the 30-kD MBD (see Fig. 15-18).[533] There is considerable evidence that the interaction exists in vivo: (1) protein 4.1R–deficient red cells are also deficient in GPC/D[533]; (2) any residual GPC/D in protein 4.1R–deficient red cells is only loosely bound to the membrane skeleton and becomes tightly bound if the cells are reconstituted with protein 4.1R[533]; (3) stripped, inside-out membrane vesicles from normal red cells bind five times more protein 4.1R than vesicles prepared from red cells lacking GPC/D[534]; (4) treatment of membrane vesicles with antibodies that block the protein 4.1R–binding sites on GPC/D reduces the ability of protein 4.1R to promote spectrin-actin binding to the vesicles by 85%[535]; (5) GPC/D-deficient red cells, like 4.1R-deficient cells, are elliptocytic and mechanically unstable[308]; and (6) GPC sorts to incipient reticulocytes along with protein 4.1R during enucleation of normal red cells but is lost with the nuclei in red cells lacking protein 4.1R.[536] However, absence of GPC/D only causes very mild elliptocytosis and hemolysis, indicating that other interactions compensate for loss of the protein 4.1R–GPC/D link.

Protein 4.1R and GPC/D form a ternary complex with p55, a membrane-associated guanylate kinase (MAGUK) protein (see later). The binding of 4.1R with p55 increases the interaction of protein 4.1R with GPC/D by an order of magnitude.[537,538] Amino acids Tyr94 to Arg166 in the 30-kD MBD of protein 4.1R interact with positively charged residues within a segment (amino acids 82 to 98) of the cytoplasmic domain of GPC/D.[290,537,539] The residues Tyr214 to Glu246 of the protein 4.1R MBD bind to p55 at a positively charged, 39-amino acid segment found between the SH3 domain and the guanylate kinase domain[539]; p55, in turn, binds via its PDZ domain to C-terminal amino acids 112 to 128 of GPC/D.[290,539,540]

Protein 4.1R MBD Also Interacts with Other Red Cell Membrane Proteins

Band 3. Protein 4.1R binds band 3 at two positively charged motifs LRRRY and IRRRY located near the end of the band 3 cytoplasmic domain (see Fig. 15-7).[541] As noted earlier under “Band 3,” this interaction is structurally important, at least in fish.[218]

In vitro, protein 4.1R competes with ankyrin for binding to band 3.[218] This suggests that protein 4.1R and ankyrin bind to separate band 3 molecules and are in separate complexes at opposite ends of spectrin (see Fig. 15-6). There is considerable evidence for this idea,[222,421,486,542-545] but if it is true then displacement of protein 4.1R from band 3 should weaken the membrane. Instead, it increases membrane mechanical stability and decreases membrane deformability.[218] This could be explained if spectrin is folded in situ so that the ankyrin complex and the actin junctional complex are adjacent to each other and the protein 4.1R–band 3 interaction modulates the association of band 3 with ankyrin. Then removal of protein 4.1R from band 3 would increase the more potent ankyrin–band 3 interaction. Further investigation is needed.

CD44. The MBD also binds to CD44, a transmembrane glycoprotein found in erythroid and nonerythroid cells. The red cell only contains about 6,000 to 10,000 molecules of CD44. The binding sites on CD44 are positively charged motifs SRRRC and QKKKL, which are homologous to the interacting site for protein 4.1R found in band 3 (discussed earlier).[546] Analogous to band 3, protein 4.1R competes with ankyrin for CD44 binding and may thus regulate CD44-ankyrin interactions.[546]

NHE1. At least one transporter, the Na^+-H^+ exchanger (NHE1), binds to protein 4.1R via the MBD in the red cell and is inhibited on binding.[547,548] Red cells from mice lacking protein 4.1R are dehydrated and have a high intracellular Na^+ content owing to hyperactivity of NHE1.[549] Some argue that a major function of protein 4.1R is to regulate ion channels.[538,548]

Phosphorylation. Protein 4.1R is phosphorylated in vitro and in vivo by protein kinase A, protein kinase C, and a tyrosine kinase. Protein 4.1R phosphorylation by protein kinase A, which labels Ser331 in the 16-kD domain and Ser467 in the 10-kD domain, inhibits the ability of protein 4.1R to promote the spectrin-actin interaction.[115,550,551] The interaction is also inhibited by tyrosine phosphorylation at Tyr418, which is located in the 10-kD domain.[552] Protein kinase C phosphorylation of protein 4.1R blocks the interaction with band 3[553] and GPC.[550]

Calmodulin Regulation. The MBD contains Ca^{2+}-dependent and Ca^{2+}-independent calmodulin (CaM)-binding sites (see Fig. 15-18, *B*).[554] At physiologic concentrations of Ca^{2+} ($<0.1\ \mu M$), CaM only binds to the Ca^{2+}-independent site. That site stabilizes the MBD.[555] As Ca^{2+} levels rise above 1 μM, CaM binds to the Ca^{2+}-dependent site, where it reduces the affinity of protein 4.1R for band 3,[554] GPC,[537] p55,[537] NHE1,[547] and CD44.[546] The crystal structure of the MBD domain of protein 4.1R (see Fig. 15-18, *B*) localizes the various binding sites.[556]

The proximity of the calmodulin-like EF hands on α spectrin to the calponin homology domains on β spectrin, where protein 4.1R binds (see Fig. 15-17), raises the interesting possibility that the spectrin EF hands interact with either the Ca^{2+}-sensitive or Ca^{2+}-insensitive calmodulin-binding sites on protein 4.1R.

Protein 4.1R Interacts with the Plasma Membrane through Direct Associations with Phosphatidylserine and the Polyphosphoinositides. Protein 4.1R binds to PS in a two-step process in which protein 4.1R first interacts with serine head groups through the positively charged amino acids YKRS in the MBD domain and subsequently forms a tight hydrophobic interaction with fatty acid moieties.[557] Importantly, acyl chain interactions with protein 4.1R impair its ability to interact with band 3, GPC, and calmodulin.

Protein 4.1R also interacts with PIP_2 via its MBD domain.[558] PIP_2 enhances binding of protein 4.1R to the second actin-binding (calponin homology) domain of β spectrin.[473] The lipid also increases binding of protein 4.1R to GPC and inhibits its binding to band 3[558] and apo-calmodulin.[558a] Further, GPC is more readily extracted by Triton X-100 from ATP-depleted red cells, implying that the protein 4.1R–GPC interaction may be regulated by PIP_2 in situ.

C-Terminal Domain

Although the functions of the spectrin-actin–binding domain and membrane-binding domain of protein 4.1R are relatively well studied, the functions of the 16-kD domain and C-terminal domain in the red cells are poorly understood. Several human mutations in the protein 4.1R C-terminal domain are known,[559] but they reduce the amount of functional protein in the red cell rather than affect its function. As previously mentioned, the C-terminal domain is slowly deamidated at Asn502 during the red cell’s life span and is glycosidated (O-linked) with *N*-acetylglucosamine.[560] It also contains a consensus sequence for binding to FKBP13, an immunophilin that is enriched in red cell membranes.[560] The consequences of all these changes are unclear.

4.1 Genes

There are four paralogous genes in the 4.1 family: 4.1R, 4.1G, 4.1N, and 4.1B.[561-564] They have recently been reviewed.[565]

The human 4.1R gene, designated *EPB41*, maps to human chromosome 1p36.1 and is more than 200 kb in length. 4.1R is the erythroid form of protein 4.1 but is expressed in some nonerythroid cells in the brain, kidney, heart, and stomach[566,567] and has a number of interesting nuclear and cytoplasmic functions in nonerythroid cells, a discussion of which that is beyond the scope of this chapter.

4.1G is the closest paralogue to 4.1R and is widely expressed, including at low levels in erythroblasts.[168,568] 4.1N and 4.1B are primarily neuronal homologues of 4.1R and are mostly localized to specific cells within the brain, although some 4.1B is expressed late in erythropoiesis.[168] The 4.1 proteins are required for the correct cell surface accumulation of a very wide variety of membrane proteins and appear to act as hubs for membrane protein organization.

Alternative Splicing of the 4.1R Gene. The 4.1R gene contains at least 24 exons, 13 of which are alternatively spliced.[569-571] This produces a very complex mixture of isoforms (see Fig. 15-18, *A*). The two major isoforms of 4.1R derive from alternate use of two distinct translation initiation codons. The 17-base pair motif at the 5′ end of exon 2 encodes an in-frame ATG start site utilized by early erythroid cells and most nonerythroid cells to produce a 135-kD 4.1R isoform that contains a 209-amino acid N-terminal extension called the headpiece (HP) domain. The upstream translation initiation sequence is spliced out late in erythroid differentiation, and a downstream ATG is used instead, producing the prototypical 80-kD isoform of 4.1R found in mature red cells.[572,573] Selective incorporation of exon 16 late in erythroid differentiation inserts a 21-amino acid sequence into the 10-kD domain of 4.1R, generating the domain essential for spectrin-actin binding. Other alternatively spliced forms of 4.1R exist in nucleated cells. Understanding the functional differences in all the 4.1R spliceoforms is a daunting challenge.

4.1R Mutations

Mutations in the human 4.1R gene cause a subset of hereditary elliptocytosis (see Chapter 16) and underscore the relevance of 4.1R to the cellular physiology of erythrocytes.

Protein p55

Protein p55 (or MPP1) (gene name *MPP1* for membrane-palmitoylated protein 1) is a MAGUK (membrane-associated guanylate kinase) homologue found in the red cell membrane as part of a ternary complex with GPC (and probably GPD) and protein 4.1R.[574] The *MPP1* gene is located on Xq28 just distal to the factor VIII locus.[575] The protein is heavily palmitoylated on cysteine residues (*S*-palmitoylation), which contributes to its tight association with the plasma membrane.[153]

p55 contains an N-terminal PDZ domain, an SH3 domain, a positively charged central (“HOOK”) domain, a tyrosine phosphorylation zone, and a C-terminal guanylate kinase domain (Fig. 15-19).[576] The PDZ domain interacts with the C-terminus of glycophorin C/D.[290,291] The positively charged HOOK segment binds the 30-kD domain of protein 4.1R. Interestingly, this domain is conserved in other MAGUK proteins.[539] It is not known whether p55 shares other functional characteristics with MAGUKs, which participate, for example, in ion channel clustering, signal transduction, and regulation of cell proliferation and tumor suppression. It is clear, however, that p55 forms a tight complex with GPC/D and protein 4.1R,[577] such that red cells lacking either 4.1R or GPC/D are also deficient in p55.[309]

There are roughly 80,000 copies of p55 per red cell,[153] and the molecule is probably a homodimer because some dimer is evident on SDS gels.[153] If so, the number of p55 molecules is approximately the same as the number of F-actin protofilaments (see later section “Organization of the Membrane Skeleton”). Either way, it is much less than the number of GPC/D and 4.1R molecules (~200,000).

p55 is heavily palmitoylated on cysteine residues by DHHC17, the only acyltransferase in red cells.[578] Two rare patients who lack DHHC17 have a mild stomatocytic hemolytic anemia with no detectable palmitoylation of p55 or other membrane proteins.[578] The amount of p55 is normal in their isolated membranes and membrane skeletons, indicating that palmitoylation is not needed to properly localize the protein. But, the “lipid rafts” (i.e., the amount of lipid remaining after extraction of membranes with nonionic detergents) are markedly decreased. Chemical suppression of protein palmitoylation in normal red cells reproduces this finding in vitro. The data indicate that palmitoylation of p55 or some other membrane protein is important in the organization of lipid rafts.

Adducin

Adducin is a heteromeric membrane skeleton protein that caps actin, regulates spectrin-actin assembly, and aids in attaching the membrane skeleton to the lipid bilayer through band 3 and Glut1. Adducin is composed of an 81-kD α subunit that associates with an 80-kD β subunit or, to a lesser extent, with a 70-kD γ subunit.[579,580] The predominant form of adducin in red cells is probably the αβ heterodimer,[135] although the $\alpha_2\beta_2$ heterotetramer may also occur. Whereas α- and γ subunits are widely expressed, β adducin is selectively expressed in brain and hematopoietic tissues.[580-582] Adducin subunits all contain three distinct domains (Fig. 15-20).[580,583] The N-terminal 39-kD domain forms the globular head. It is protease resistant and generally more basic than the remainder of the protein.[584] A 9-kD neck links the N-terminal domain to the 30-kD C-terminal tail. The tail is flexible, protease sensitive, and composed almost entirely of hydrophilic residues. It contains a highly basic 22-residue C-terminal motif homologous to the myristoylated alanine-rich C kinase substrate (MARCKS) protein (see Fig. 15-20).[580] There are multiple alternative

spliceoforms of adducin subunits, many of which generate truncated isoforms that may serve tissue-specific functions.[585-587]

Adducin Binds, Bundles, and Caps Actin, in Addition to Enhancing the Association of Spectrin with Actin. The adducin head domains form a globular core,[583] linked by the neck domains, which contain an oligomerization site.[588] Adducin interacts directly with the fast-growing (barbed) ends of actin filaments and caps filament growth, stabilizing the filaments.[589] Both the C-terminal MARCKS domain and the neck domain are required for actin binding.[588] The numbers of adducin dimers and actin protofilaments are equivalent (~30,000 per red cell), consistent with its capping function.

The adducin tails also recruit spectrin to the fast growing (barbed) ends of actin.[588,590] Adducin binds to the N-terminal actin-binding domain of β spectrin and the adjacent two β-spectrin repeats.[475] However, the fact that mutations within the last few repeats of α spectrin markedly reduce membrane adducin content[476] suggests that the C-terminus of α spectrin also contributes to adducin binding.

Adducin Attaches to Band 3, Stomatin, Chorein, and the Glucose Transporter and Helps Anchor the Membrane Skeleton

Band 3. The C-terminal tail of adducin also binds to the subset of band 3 dimers located near the actin junctions.[222] α-Adducin and β-adducin tails can both bind to band 3 dimers in a 1 : 1 complex.[222] It is not known whether intact adducin can bind two band 3 dimers or just one.

The importance of the band 3-adducin interaction is unclear. Band 3 null mice have a 35% deficiency of adducin and, as noted earlier, some of the mice with α-spectrin C-terminal mutations have an even greater deficiency. This suggests the interaction is important, although care must be taken in deducing the importance of an interaction (or lack thereof) from changes in mouse mutants given the multiple interactions of most membrane skeleton proteins. For example, band 3 null mice have near-normal amounts spectrin[220] but no one would argue that the several attachments of spectrin to band 3 are not important. A better argument is that adducin tail fragments introduced into red cell membranes interfere with the normal adducin–band 3 interaction and weaken the membrane.[222] On the other hand, knockout of all adducin genes produce, at best, a very mild hemolytic anemia (see later).

The band 3–adducin interaction is sensitive to Mg^{2+} over the range of concentrations found in the red cell.[222] Free Mg^{2+} ranges from approximately 4 mM in deoxygenated red cells when 2,3-diphosphoglycerate (2,3-DPG) is bound to hemoglobin to much lower concentrations in oxygenated cells when 2,3-DPG is available to bind Mg^{2+}. This suggests that the mechanical properties of the red cell membrane may be regulated by oxygenation, although whether the binding changes in seconds, as would be needed under normal circulatory conditions, is unknown.

Stomatin and Glut1. As noted earlier, stomatin binds to some of Glut1 molecules and converts them to dehydroascorbic acid channels. Glut1 also binds to adducin[420] and dematin,[420] and there is preliminary evidence, never published in full, that stomatin binds to adducin.[591] The interactions are not as well characterized as the interaction of adducin with band 3, but it is reasonable to assume that they also help attach actin junctions to the membrane.

NHE1. The Na^+-H^+ exchanger (NHE1 or SLC9A1) is markedly deficient in β-adducin knockout mice,[592] suggesting the two molecules interact. As noted earlier, NHE1 also binds to protein 4.1R.[549]

Chorein. Mutations in chorein cause chorea-acanthosis, a disease characterized by striatal neurodegeneration and acanthocytic red cell morphology (see Chapter 37). Chorein is the protein product of the vacuolar protein sorting homolog A gene (gene symbol *VPS13A*). The functions of chorein in the red cell are not understood, but it was recently discovered that it binds to both β adducin and β actin,[592a] which would place it in the actin junctional complex. Since β adducin is only expressed in brain and hematopoietic tissues and the phenotype of chorea-acanthocytosis is limited to those tissues, the interaction of chorein with β adducin may be important.

Adducin Activity is Regulated by Phosphorylation and Ca^{2+}-Calmodulin. The C-terminal MARCKS domain contains a serine phosphorylation site targeted by both protein kinase A (PKA) and protein kinase C (PKC).[593] There are also three additional PKA sites located in the neck domain of α adducin (see Fig. 15-20).[593] PKA phosphorylation reduces both the affinity of adducin for spectrin-actin complexes and the ability of adducin to enhance spectrin-actin binding.[593] Phosphorylation of the MARCKS domain by PKC inhibits actin-capping activity and prevents adducin-mediated recruitment of spectrin to actin protofilaments.[594]

The MARCKS domain also contains a Ca^{2+}-dependent calmodulin binding site.[593] PKA or PKC phosphorylation of the MARCKS domain inhibits calmodulin binding.[593] Calmodulin binding reduces both adducin-actin binding and adducin-mediated enhancement of spectrin-actin binding.[590] Calmodulin also blocks the binding of a second spectrin molecule to an adducin/actin/spectrin complex.[579] Once bound to the MARCKS domain, calmodulin reduces the rate of PKA phosphorylation of β adducin and of PKC phosphorylation of α and β adducin.[593] Despite these many complex in vitro regulatory effects, it appears that PKC phosphorylation of adducin has little effect on red cell membrane mechanical stability.[550]

α Adducin is also subject to Rho kinase phosphorylation (see Fig. 15-20), which enhances the interaction of α adducin with actin filaments and spectrin. Myosin phosphatase dephosphorylates α adducin, but this activity is inhibited by Rho kinase–mediated phosphorylation of myosin phosphatase.[595]

Thus adducin activity is tightly regulated in vivo by Ca^{2+}-dependent calmodulin binding and a complexity of differential phosphorylation states. In general, Rho kinase phosphorylation tends to foster adducin interaction with actin and spectrin and PKA/PKC phosphorylation or calmodulin binding tends to inhibit them.

Red Cells Lacking Adducins Are Similar to Erythrocytes from Patients with Mild Hereditary Spherocytosis. Mice with a targeted deletion of β adducin have a *very* mild anemia with osmotically fragile, spherocytic, and dehydrated red cells.[582] Incorporation of α adducin into the membrane skeleton is decreased by 30%, perhaps owing to decreased α-subunit stability in the absence of its heteromeric partner.[582] Interestingly, there is a compensatory fivefold increase in the amount of γ adducin associated with the red cell membrane skeleton.[582] However, knockout of γ adducin has no hematologic phenotype and the combined βγ-adducin knockout is not worse than loss of β adducin alone.[596] Knockout of α adducin, which eliminates all three adducins (α, β, and γ), still results in only mild hemolysis and moderate spherocytosis, although is slightly more severe than in the β-adducin knockout.[223] There are other problems, including hydrocephalus.[223] However, the loss of both β adducin and the dematin headpiece (see later) does produce a severe spherocytic hemolytic anemia. On the other hand, loss of the dematin headpiece alone has minimal effect.[597] These data, combined with the evidence that red cells lacking GPC have, at most, very mild hereditary elliptocytosis, suggest the various vertical membrane connections involving the actin junctions are largely redundant and only become consequential when more than one is eliminated.

Dematin (Protein 4.9)

Dematin is a widely expressed actin-binding protein that bundles actin filaments into cables[598] (although presumably not within the red cell membrane skeleton) and aids in spectrin-actin binding.[477] Red cells contain both 48-kD and 52-kD spliceoforms.[599,600] The latter form contains an extra 22-amino acid insert. Dematin is composed of two domains: an unstructured N-terminal tail or “core” domain, and a C-terminal actin-binding headpiece that shares homology with villin, an actin-bundling protein in the epithelial brush border.[600] The 22-amino acid insertion contains an ATP-binding site within a conserved 11-amino acid motif that is also found in protein 4.2.[601]

Dematin is generally believed to be a trimer of two 48-kD subunits and one 52-kD subunit held together by disulfide bonds.[598,599,602] However, recent evidence indicates it is monomeric.[602a] Dematin monomers contain two actin filament binding sites: one in the headpiece domain[602b] and one in the tail.[602a] Dematin is phosphorylated by PKA and PKE.[603] PKA phosphorylation of Ser 381 in the headpiece causes the headpiece to bind to the tail, blocking one of the actin binding sites and eliminating actin filament bundling but not actin bonding activity.[602a] PKA phosphorylation at Ser 74 in the dematin tail also abolishes dematin’s actin bundling capability.[602,604] The mechanism of this effect has not been investigated.

Importantly, dematin also has functions in red cells other than actin bundling. First it binds to the cytoplasmic domain of the glucose transporter, Glut1, and presumably helps attach the actin protofilaments to the membrane. Second dematin, but not PKA-phosphorylated dematin, binds to the spectrin tail and facilitates the interaction of spectrin with actin.[477] The interaction sites in these two interactions have not yet been determined.

Rho GTPases regulate actin organization, and dematin interacts with the Ras–guanine nucleotide exchange factor Ras-GRF2 in extracts from brain. This blocks transcriptional activation of Jun by Ras-GRF2 and activates ERK1 via a Ras-GRF2–independent pathway.[605] It is not clear if these pathways operate in mature red blood cells; if they do, dematin may help regulate actin organization within the membrane skeleton.

As noted earlier, knockout of the dematin headpiece results in a *very* mild spherocytic hemolytic anemia,[597] suggesting that the spectrin and actin binding activities of dematin are either redundant or not critical for membrane stability.

Tropomyosin

Tropomyosin (TM) is a dimeric protein that functions in red cells to stabilize and limit F-actin protofilaments to uniform segments measuring 37 nm—the length of tropomyosin molecule.[159,160,606] The α-helical subunits of TM form a rodlike coiled coil. The two major human TM isoforms found in red cells are designated hTM5 (or TM5NM1) and hTM5b (or TM5b) and derive from the *TPM3* (or γ-TM) and *TPM1* (or α-TM) genes, respectively (Fig. 15-21).[160] They migrate as two closely spaced bands in the region of band 7 on SDS gels (see Fig. 15-5).[156] hTM5 is the upper band. hTM5 and hTM5b are present in an equimolar ratio. Both have high affinities for F-actin and tropomodulin. They are shorter than muscle TMs.

Each F-actin protofilament binds two homodimeric[606a] TM molecules in an Mg^{2+}-dependent manner, such that one TM dimer binds to each of the actin filaments contained in the F-actin double helix.[156] Thus all of the actin protofilaments within the red cell membrane skeleton are coated with TM, which strengthens the filamentous network. Each TM dimer is just long enough to cover the estimated seven actin monomers in one of the two strands of a red cell F-actin protofilament. This supports the hypothesis that TM functions as a molecular ruler, along with actin-capping proteins, in dictating the length of the actin protofilaments. There are approximately 140,000 TM monomers per red cell, which corresponds to 70,000 heterodimers and 35,000 double-helical actin filaments. This corresponds to 490,000 actin monomers at a 1 : 7 ratio, which is close to the measured number of 500,000.

The N-terminus of TM binds avidly to tropomodulin, the capping protein for the pointed or slow-growing end of actin. Two TM heterodimers bind per tropomodulin in a cooperative manner.[607] This interaction limits the cooperativity of actin-TM associations, thereby restricting the length of actin filaments beyond the length of TM itself.[608] The binding of TM to actin is unaffected by spectrin, but spectrin-actin interactions are inhibited by saturating concentrations of TM,[609] and red cell membranes that lack TM are markedly more fragile than

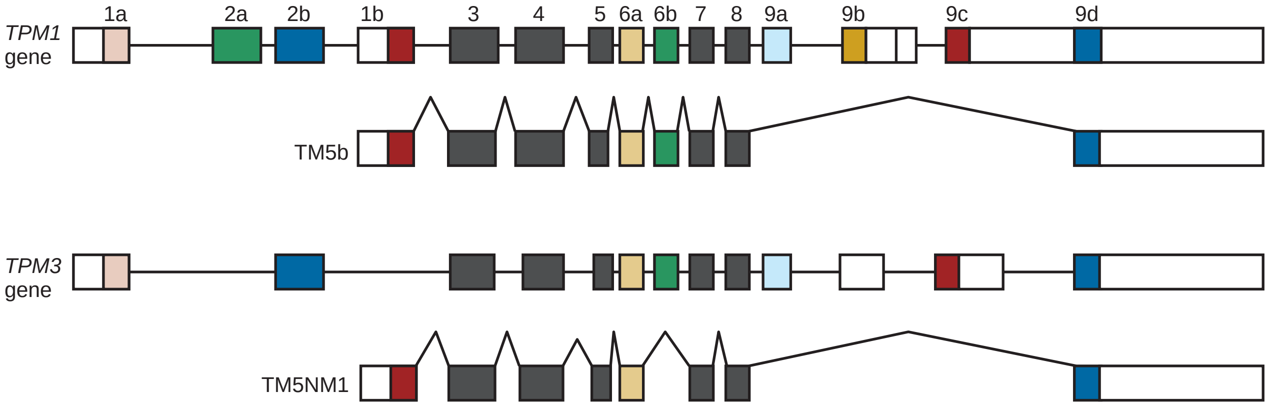

Figure 15-21 Gene structure of the red blood cell tropomyosins *(TM)*. There are more than 40 isoforms of tropomyosin, which derive from four TPM genes.[159] Red cells contain two of these. One is derived from the *TPM1* gene and is called TM5b or hTM5b. The other is derived from the *TPM3* gene and is named TM5NM1 or hTM5.

normal.[610] The actin-binding domain of β spectrin is more easily exchanged into the membrane skeleton of TM-depleted red cell membranes, indicating that TM strengthens spectrin/actin/protein 4.1R binding.[610] Only endogenous TMs, and not the longer muscle isoforms, can restore mechanical stability to the TM-depleted membranes. These findings indicate that actin-TM interactions dictate the site specificity, strength, and/or extent of spectrin binding along the actin filament and that endogenous TMs are required for these effects.

Tropomodulin

Tropomodulin-1 (TMod1) is a 41-kD protein that functions as an actin-capping protein at the pointed or slow-growing end of actin filaments.[611] The C-terminal end of TMod1 has pointed-end actin-capping activity. The N-terminal portion binds with high affinity to TM,[607] which greatly strengthens actin capping.[612] One TMod1 molecule binds to each of the two F-actin/TM strands in the actin protofilament. Among TM homologues, TMod1 binds with highest affinity to the shorter nonmuscle erythrocyte isoforms (hTM5 and hTM5b) and not as well to the longer muscle TMs.[160,608,613] The interaction of TMod1 with TM inhibits the head-to-tail associations of TM molecules along actin filaments, thereby restricting the lengths of TM-stabilized actin filaments.[614] TMod remains attached to the red cell membrane even after removal of spectrin, actin, and TM. The membrane-binding site for TMod1 and the significance of this membrane interaction are unknown.

Mice that lack TMod1 have mild spherocytic elliptocytosis that is more spherocytic than elliptocytic.[615] The phenotype may be ameliorated by an increase in TMod3, which is not normally expressed in mature red cells, to about 20% of the normal level of TMod1. Surprisingly, TMod1-null erythrocytes have normal levels of actin, TMs, adducins, and other membrane skeleton proteins. However, actin filament lengths are variable and the membrane skeleton contains abnormally large and variable pore sizes,[615] proving that TMod1 is critical for maintaining normal actin filament length and skeleton architecture.

Although TMod3 is not normally expressed in mature red cells, it is important in erythropoiesis. Mice that lack the TMod3 gene die in utero due to impaired terminal erythroid differentiation in the fetal liver.[615a] The late erythroblasts have multilobular nuclei, they assemble actin aberrantly during enucleation and enucleate poorly, and they do not form erythroblast islands well.

Ankyrin

Erythrocyte ankyrin (ankyrin-1 or ankyrin-R) is a 206-kD protein[616] that links spectrin to band 3 and thus forms the basis of the skeleton-membrane attachment so critical to the mechanical and viscoelastic properties of the red cell. Ankyrin-R is encoded by the *ANK1* gene, which is located on the short arm of chromosome 8 near the centromere (8p11.2).[617] The protein is composed of three domains: an 89-kD membrane domain (amino acids 2 to 827) that interacts with band 3 (and other integral membrane proteins in nonerythroid cells), a 62-kD spectrin-binding domain (amino acids 828 to 1382), and a 55-kD C-terminal domain (amino acids 1383 to 1881) that is believed to modulate ankyrin's interactions with spectrin and band 3 (Fig. 15-22). Alternative splicing, particularly in the C-terminal domain, generates several ankyrin species in the red cell and accounts for the presence of ankyrin bands 2.1, 2.2, 2.3, and 2.6 on SDS gel electrophoresis (see Fig. 15-5).[616] Disruption of the ankyrin-band 3 interaction by exposing intact red cells to alkaline pH causes marked membrane instability, emphasizing the importance of the ankyrin linkage to red cell physiology.[618] Indeed, defects in ankyrin are the most common cause of hereditary spherocytosis[619] (see section on "Hereditary Spherocytosis" in Chapter 16).

Membrane Domain

Ankyrin Repeats Are Found in Hundreds of Proteins in All Phyla and Are One of the Most Common Protein Sequence Motifs. The membrane domain is composed of a tandem array of ankyrin repeats.[620] Similar repeats function as sites of protein-protein interactions in a broad range of proteins involved in development, cell cycle control, oncogenesis, transport, and many other

Figure 15-22 Ankyrin structure and interactions. **A,** Model of erythroid ankyrin (Ank1 or AnkR) structure. The *membrane domain* (89 kD) contains 24 "Ank" repeats (33 amino acids each), grouped functionally into subdomains of six repeats. Their consensus sequence is shown at the *top left* in single-letter amino acid code. *Dashes* indicate less-conserved residues. There are two binding sites for band 3, one involving repeats 7 to 12 (SD1, subdomain 1) and one involving repeats 13 to 24 (SD2). The ankyrin-binding loops on band 3 are predicted to interact with ankyrin repeats 19 and 20 *(light blue)* of SD2. The interaction site within SD1 is not known. The *spectrin domain* (62 kD) contains three subdomains (ZU5A, ZU5B, and UPA). ZU5A *(light blue)* forms the binding site for spectrin. The *C-terminal (regulatory) domain* (55 kD) is believed to modulate the binding functions of the other two domains. A conserved death domain (DD) resides at the beginning of this domain. It is similar to death domains in proteins involved in apoptosis, but its function in ankyrins is unknown. In the middle of the domain a highly acidic inhibitory region in exon 38 is spliced out of full-length ankyrin (ankyrin 2.1) to make ankyrin 2.2. At least eight isoforms of the last three exons exist. In addition, isoforms lacking exons 38 and 39, 36 through 39, and 36 through 41 have been detected. The *asterisk* and *vertical line* under it indicate the location of the translation terminator codon. The *inset* shows the structure of four consecutive ankyrin repeats. Each repeat forms an L-shaped structure. A β-hairpin loop *(arrows)* makes up the bottom of the L, and two antiparallel α-helical coils form the vertical stem. The hairpin loops of neighboring repeats interact to create an antiparallel β-sheet, and the α-helices interact to form helical bundles. The *small triangles* in the inset indicate the junction between adjacent repeats. **B,** Model of the whole membrane domain based on the structure of half the domain and viewed along the spiral axis. Repeat 1 is red, and repeat 24 is violet. **C,** Model of the interaction between a dimer of the cytoplasmic domain of band 3 *(green)* and repeats 13 to 24 of ankyrin *(red)*. *(**B,** from Michaely P, Tomchick DR, Machius M, et al: Crystal structure of a 12 ANK repeat stack from human ankyrin*$_R$*.* EMBO J *21:6387–6396, 2002;* ***C,*** *from Grey JL, Kodippili GC, Simon K, et al: Identification of contact sites between ankyrin and band 3 in the human erythrocyte membrane.* Biochemistry *51:6838–6846, 2012.)*

functions.[620-622] Ankyrin repeats form a novel L-shaped structure consisting of a β-hairpin (bottom of the L) followed by two α helices that pack side to side in an antiparallel fashion (stem of the L) (see Fig. 15-21, *A*).[623] In ankyrin, the repeats correspond to individual exons.[624] They start at the tip of the β hairpin and line up side to side like overlapping Ls, with the hairpins forming a β sheet that is perpendicular to the plane of the α helices. The concave and convex surfaces of the connected repeats provide an ideal interface for protein-protein interactions, making the ankyrin repeat a versatile binding partner. A model of the 24 repeats of ankyrin resembles one twist of a spring (see Fig. 15-21, *B*),[623] and mechanical studies show that ankyrin repeats have springlike properties.[625] Some speculate they may link external mechanical forces to signal transduction or changes in ion transport.[625,626]

The 89-kD N-terminal Domain of Ankyrin Contains 24 Consecutive 33 Amino Acid Repeats.[616] In ankyrin, the ankyrin repeats are organized functionally into four subdomains of six repeats each (see Fig. 15-22, *A*)[627] and contain two distinct and cooperative binding sites for band 3.[628] One band 3–binding site occurs within repeats 7 to 12 (subdomain 2) and the other within repeats 13 to 24 (subdomains 3 and 4) (see Fig. 15-22, *A*). It is clear the ankyrin binds four molecules of band 3,[211-213] but whether this is a single band 3 tetramer or two independent dimers is not certain. We favor the former model because stable band 3 tetramers can be isolated from red cell membranes and the numbers correspond to the number of ankyrin molecules.[213,214] The high-affinity binding interface for ankyrin on the cytoplasmic domain of band 3 (kD ~ 10^{-7} to 10^{-8} M) has been localized to a pair of adjacent β-hairpin loops in the cytoplasmic domain of band 3 formed by amino acids 63 to 73 and 175 to 185 (see Figs. 15-7 and 15-9).[207-209] Computer simulations and mutation studies predict that these loops contact residues in ankyrin repeats 19 and 20 within subdomains 3 and 4 (see Fig. 15-22, *C*).[209] A similar prediction was obtained with a spin-label approach.[215] The specific repeats that mediate binding within subdomain 1 have not been identified. There is evidence that ankyrin also interacts with other band 3 residues near the two loops[209] and with the N-terminus of band 3.[207,228,232,535,618] The importance of these interactions is unknown.

Removal of the 75- to 185-amino acid loop of band 3 abolishes affinity for ankyrin in vitro.[207] Surprisingly, however, red cells containing the loop-deleted band 3 are only mildly spherocytic and unstable, much less so than red cells that lack ankyrin or band 3.[629] This suggests that either the other interactions between ankyrin and band 3 are more important in vivo than in vitro or that other interactions compensate. Both explanations are probably true. First, although the single 63-to 73-amino acid loop and its neighboring sites are too weak to maintain the ankyrin/band 3 complex at in vitro concentrations, they will be much stronger under the vastly higher protein concentrations that exist on the membrane. Second, there are other connections between the membrane skeleton and the multiprotein band 3/ankyrin complex (see Fig. 15-6). Both ankyrin and band 3 interact with protein 4.2 (see later), and ankyrin and 4.2 both interact with spectrin and with elements of the Rh complex, especially RhAG.[332,386,630] Ankyrin also interacts with CD44.[546]

Spectrin Domain

The central 62-kD domain of ankyrin binds to β spectrin and attaches the spectrin-actin–based skeleton to the plasma membrane. Ankyrin-spectrin interactions are cooperative, such that ankyrin binding promotes spectrin tetramer and oligomer formation.[631,631a] The attachment of ankyrin to spectrin dimers causes a tenfold increase in the self-association.[631a] However, cleavage of the ankyrin–band 3 linkage also weakens spectrin self-association,[631b] perhaps indirectly by increasing the mobility of the otherwise attached spectrin dimer. This would lead to a lower local two-dimensional concentration of the dimer, diminishing its chances of finding a partner and forming a tetramer. Presumably both of these mechanisms operate to regulate the relatively tenuous self-association interaction.

The spectrin domain is composed of two tandem ZU5 subdomains followed by a UPA subdomain (see Fig. 15-22, *A*). The spectrin-binding site occurs at a conserved, positively charged surface patch within ZU5A.[467-469] This site attaches to repeats 14 and 15 of β spectrin, especially to the C helix of repeat β14, and the loop between helices B and C of β spectrin repeat 15 (see Fig. 15-13, *C*). Repeat β15 forms an unusual angle with repeat β14, and the ZU5A domain nestles into the corner formed by the two repeats.[469]

The ZU5B domain extends away from ZU5A on the side opposite the spectrin binding face. It does not directly interact with ZU5A and does not influence spectrin binding.[632-633] The location of the UPA subdomain has not been studied in red cell ankyrin, but in another ankyrin (ankyrin-B) it folds back and lies adjacent to ZU5A.[633] Like ZU5B, the UPA subdomain does not affect spectrin binding.[633] The functions of ZU5B and UPA in red cells are unknown, but they have conserved binding surfaces that suggest they bind to as yet undiscovered proteins. A few missense mutations in these subdomains have been found in patients with hereditary spherocytosis,[633] which supports the idea that they are functionally important.

C-Terminal (Regulatory) Domain

The 55-kD C-terminal domain contains sequences that regulate ankyrin interactions[634,635] and has been dubbed the "regulatory domain."[616] Alternative splicing within the C-terminal domain yields at least 15 ankyrin isoforms differing in size and, presumably, functions (see Fig. 15-22, *A*).[624] For example, one isoform of ankyrin, represented by band 2.2, lacks an acidic 162-amino acid peptide present in full-sized ankyrin (band 2.1). Omission of this sequence generates an activated ankyrin, which exhibits enhanced binding to band 3 and spectrin[635] and facilitates the binding of ankyrin to additional targets in nonerythroid membranes.[636] The identification of a membrane-associated protease that cleaves ankyrin suggests that cleavage of a repressor region within the C-terminal domain may activate ankyrin.[636] The C-terminal domain also contains a region homologous to the "death domain" of proteins implicated in apoptosis,[637] suggesting that ankyrins may additionally play a role in this signaling pathway. The death domain lies just beyond the spectrin domain but does not interact with it.[633] Its function in red cell ankyrin is unknown.

Phosphorylation and Hydroxylation

The effect of phosphorylation on ankyrin function has not been studied in recent years, but there are old studies showing that the protein can be phosphorylated by casein kinase I[638] and casein kinase II.[639] Unphosphorylated ankyrin preferentially binds to spectrin tetramers and oligomers rather than spectrin dimers.[631,638,640] This preference is abolished by phosphorylation, which also reduces the capacity of ankyrin binding to band 3.[641]

The protein called factor-inhibiting hypoxia-inducible factor catalyzes β-hydroxylation of several asparagine residues erythrocyte ankyrin and multiple other proteins containing ankyrin repeats.[642] The modification stabilizes the membrane domain and inhibits band 3 binding. Its physiologic significance is unknown.

Ankyrin Genes

There are three human ankyrin genes: *ANK1, ANK2,* and *ANK3*. The corresponding proteins, ankyrin-R (ankyrin-1),[616] ankyrin-B (ankyrin-2),[643] and ankyrin-G (ankyrin-3),[644,645] have multiple spliceoforms and distinct patterns of expression in the body.

Ankyrin-R is primarily expressed in erythrocytes, but it is also found in muscle cells, macrophages, endothelium, and specific neuronal populations, particularly Purkinje and granule cells of the cerebellum.[646] Ankyrin-B and ankyrin-G are expressed in most cells other than red cells, but they have distinct functions. A discussion of the large literature on these two proteins is beyond the scope of this chapter but reviews are available.[426,647,648]

Overall, the nonerythroid ankyrins link the spectrin-actin–based skeleton to a large number of structurally diverse integral membrane proteins, mostly through their versatile ankyrin repeats.[622,649,650] Examples include many transporters and channels, various receptors, and a number of adhesion molecules. There is no specific motif that specifies an ankyrin-binding site in these proteins. They seem to have developed by convergent evolution. Ankyrin-B and ankyrin-G not only attach integral proteins to the spectrin skeleton but in many cases also localize them to distinct domains and subcellular compartments. This may be why so many spliceoforms exist.

Ankyrin-1 Mutations

Mice With Normoblastosis (nb/nb) Produce a Defective Ankyrin That Causes a Severe Hemolytic Anemia. Red cells from nb/nb mice contain a nonsense mutation in ankyrin just between the spectrin binding and C-terminal domain that leads to production of decreased amounts of a shortened (157-kD) ankyrin.[651,652] As a result, *nb/nb* red cells are moderately spectrin-deficient despite normal spectrin synthesis.[651,653] The resultant red cells exhibit severe osmotic fragility and shortened life span owing to a defective membrane skeleton. Mature nb/nb mice also develop ataxia secondary to a dropout of Purkinje cells in the cerebellum.[654]

Ankyrin-1 Mutations Are the Most Common Cause of Hereditary Spherocytosis in Humans. Erythrocyte ankyrin mutations lead to combined deficiencies of ankyrin and spectrin. The defective cells produce a variable clinical presentation ranging from mild hemolysis to severe transfusion-dependent anemia[639] (see "Hereditary Spherocytosis" in Chapter 16).

Protein 4.2

Protein 4.2 is an 80-kD peripheral membrane protein that participates in stabilizing the red cell membrane skeleton through interactions with band 3, CD47, spectrin, ankyrin, and the lipid bilayer. Protein 4.2 shares homology with transglutaminases and is part of a transglutaminase gene cluster on chromosome 15q15, but it lacks transglutaminase activity.[655,656] Like most red cell membrane proteins, its expression increases progressively throughout erythropoiesis.[168] There are eight spliceoforms that arise from alternative splicing of exon 3, exon 5, or 90 bp in exon 1.[657,658] The major form lacks the 90-bp segment. The others are all minor species in the mature red cell. The protein is found mostly in erythroid tissues[659] and in the lens.[660] Reports of protein 4.2 detected in other tissues by immunologic methods[661] are not adequately controlled for antibody cross-reactivity with tissue transglutaminases. The protein has recently been reviewed.[662]

Protein 4.2 Structure

Band 3 Binding. Protein 4.2 binds to band 3 with a kD of 10^{-6} to 10^{-7} M. The interaction increases band 3–mediated chloride transport.[663] The band 3–binding site on protein 4.2 has been mapped to amino acids 187 to 210 (Fig. 15-23).[664] This sequence encompasses a palmitoylation site on Cys203. Palmitoylation enhances band 3 binding.[219,664] The binding site for protein 4.2 on band 3 has not been clearly identified. Band 3 binding is absolutely required for 4.2 expression. Red cells that lack band 3 completely lack protein 4.2, despite normal 4.2 synthesis.[220] Conversely, band 3 is partially deficient in red cells that lack protein 4.2.[221] It is not clear whether protein 4.2 binds to the ankyrin-linked band 3 tetramers or to the "free" band 3 dimers. Studies of band 3 mobility suggest 4.2 binds to band 3 dimers, but 4.2 also binds to ankyrin, which attaches to band 3 tetramers.[665,666] Because only a fraction of the protein 4.2 remains attached to the membrane skeleton (which retains ankyrin-linked band 3 tetramers) after band 3 dimers are extracted with Triton X-100,[166] it probably binds to both.

Ankyrin Binding. Protein 4.2 and ankyrin associate in solution, and there is indirect evidence that they interact on the membrane.[667] Mice that completely lack ankyrin-1 have only a small amount of protein 4.2 on their red cell membranes.[668] Red cells expressing the unstable protein 4.2 Komatsu (Asp175→Tyr) lack 4.2, and the

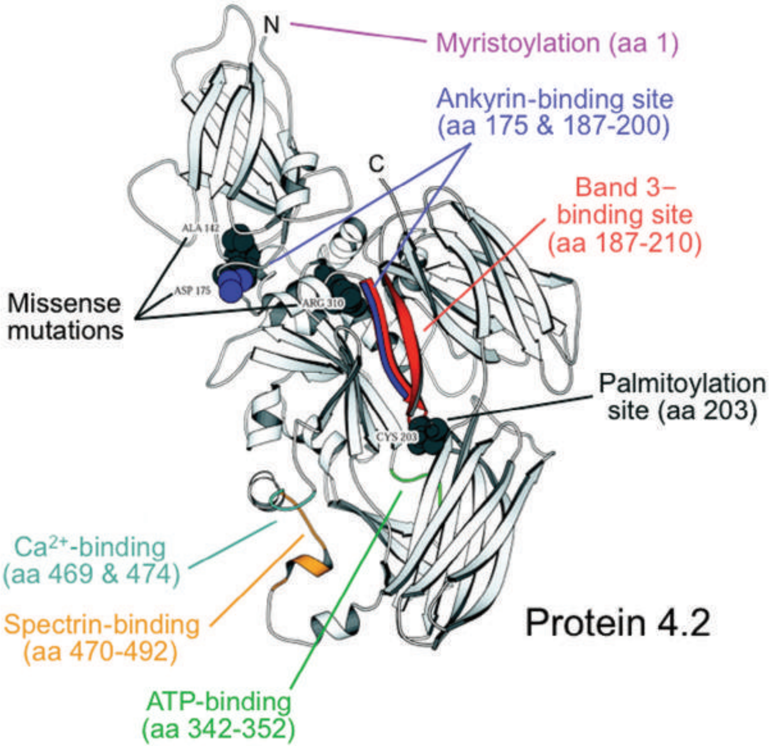

Figure 15-23 Homology model of protein 4.2 based on the known structure of a transglutaminase, with putative binding and posttranslational modification sites mapped onto the structure. The band 3– and spectrin-binding sites and the palmitoylation site are the most certain. Note that the band 3– and putative ankyrin-binding sites overlap, which raises the possibility that one influences the binding of the other. Palmitoylation, which occurs on Cys203 *(shown as a space-filled residue)*, just beyond the band 3–binding site, enhances band 3 binding. Note also that there is a likely Ca^{2+}-binding site just upstream of the spectrin-binding site. Spectrin binding to protein 4.2 is enhanced by Ca^{2+}. Patients with missense mutations of Asp175 and Arg310 *(shown as space-filled residues)* have impaired (R310Q) or absent (D175Y) ankyrin binding to protein 4.2. The location of the common 4.2^{Nippon} mutation (A142T) is also depicted. *Note:* amino acids (aa) are numbered using the full 721 amino acid sequence, even though the common spliceoform of 4.2 is only 691 amino acids long. *(Modified from Toye AM, Ghosh S, Young MT, et al: Protein-4.2 association with band 3 [AE1, SLC4A1] in* Xenopus *oocytes: effects of three natural protein-4.2 mutations associated with hemolytic anemia.* Blood *105:4088–4095, 2005.)*

recombinant protein fails to bind ankyrin.[663,669] Mapping studies locate the ankyrin-binding site to a neighboring region (amino acids 187 to 200)[670] that overlaps the first half of the band 3–binding site (see Fig. 15-23). This raises the possibility that binding of band 4.2 to ankyrin inhibits its binding to band 3. There is some evidence for this in early studies of Korsgren and Cohen, who found that coincubation of ankyrin and band 4.2 in solution partially blocked the binding of both proteins to the membrane.[667] But the question needs to be reexamined.

CD47 Binding. Protein 4.2 interacts with the Rh complex through CD47.[384-386] Red cells that lack protein 4.2 nearly lack CD47,[385,386] and patients with partial deficiency of 4.2 have less CD47 attached to the membrane skeleton. However, mice lack this association[385] (and, interestingly, protein 4.2 is easier to extract from the red cell membrane in mice). On the other hand, mice and humans with absent CD47 or low expression of the protein, do not have reduced protein 4.2.[385] This, and other observations,[332] show that the band 3 complex (band 3, ankyrin, GPA, and protein 4.2) interacts with the Rh complex (RhAG, Rh polypeptides, GPB, LW, and CD47).

Spectrin Binding. Korsgren first showed that protein 4.2 binds spectrin.[665] She identified both high-affinity (kD ~ 10^{-9} M) and low-affinity (kD ~ 10^{-7} M) sites. Reconstituting 4.2-stripped membrane vesicles with protein 4.2 increased spectrin-binding capacity from approximately 50% to approximately 80% of normal.[665] The binding site on protein 4.2 has been mapped to amino acids 470 to 492 (see Fig. 15-23).[671] This peptide contains a segment homologous to ERM proteins, like protein 4.1R. As noted in the section on spectrin, protein 4.2 binds to the EF hand domain of α spectrin in vitro.[486] Whether protein 4.2 binds to this site in vivo is not yet known, but if it does it creates an interesting dilemma because ankyrin is at one end of the spectrin heterodimer and the EF hands are at the other. An apparent Ca^{2+}-binding site lies next to the spectrin-binding site (see Fig. 15-23) and is probably functional because micromolar concentrations of Ca^{2+} triple the binding of the EF hand domain of spectrin to protein 4.2.[486]

Protein 4.1R Binding. Unpublished studies show that protein 4.2 also binds to protein 4.1R (kD ~ 1.6×10^{-6} M) in a ratio of one 4.1R molecule for every two molecules of 4.2.[672] The binding affinity is reduced about 75% by

Ca^{2+}-calmodulin. This is more evidence in favor of protein 4.2 participating in the band 3/spectrin/actin junctional complex as well as the band 3/ankyrin/spectrin complex.

Posttranslational Modifications

Protein 4.2 has a nucleotide-binding P-loop (residues 342 to 352) and binds ATP with a kD of approximately 10^{-6} M.[601] This is well below the concentration of ATP in the red cell (1.5 to 1.9 mM), so protein 4.2 should be saturated with ATP under physiologic conditions. The consequences of this binding are unknown.

Protein 4.2 is myristoylated on the N-terminal glycine[673] and is palmitoylated on Cys203,[674] which suggests the protein binds independently to the lipid bilayer. It is likely that most of the 4.2 molecules are myristylated.[673] The extent of palmitoylation is unknown. The myristoyl group seems to influence cellular localization because nonmyristoylated 4.2 does not go to the plasma membrane.[675] As noted earlier, the palmitoyl group enhances binding of protein 4.2 to band 3 at least threefold.[664]

Protein 4.2 Deficiency Is a Cause of Hereditary Spherocytosis and Ovalostomatocytosis

Mutations in the human protein 4.2 gene are associated with the production of dysmorphic and osmotically fragile red cells, resulting in hemolytic anemia (see "Hereditary Spherocytosis" in Chapter 16). Protein 4.2 null mice also have mild hereditary spherocytosis.[221]

Peroxiredoxins

There are six known mammalian peroxiredoxins (PRDX1 to PRDX6). Peroxiredoxin-2 is the most common in red blood cells and is the third most abundant protein in the cell. Peroxiredoxin-1 and peroxiredoxin-6 are present in smaller amounts. The peroxiredoxins are widely distributed and conserved in evolution. They protect cells from damage by reactive oxygen species and regulate signal transduction pathways that influence cell growth and apoptosis.[676]

Peroxiredoxin-2

Peroxiredoxin-2, also known as thioredoxin peroxidase B, calpromotin, thiol-specific antioxidant protein, protector protein, natural killer–enhancing factor B, acidic peroxidoxin, torin, and band 8, is 198 residues in length (~22 kD) and is a soluble cytoplasmic protein that translocates to the membrane in the presence of Ca^{2+}. There are approximately 14 million copies per cell,[677,678] but only about 200,000 molecules appear to be associated with the membrane in normal red cells, judging from the intensity of band 8 on SDS gels. The protein binds to the N-terminus of band 3,[183] where it remains active and presumably competes for a "parking space" with deoxyhemoglobin, multiple glycolytic enzymes, and ankyrin (see Fig. 15-7). The expression of peroxiredoxin-2 begins in early erythroid development, prior to the start of hemoglobin synthesis.[168] In common with the glutathione peroxidases, peroxiredoxins are able to reduce hydrogen peroxide and lipid hydroperoxides to water or the corresponding alcohol, respectively. The activity of peroxiredoxin 2 depends on a pair of highly conserved cysteine residues that catalyze the peroxide reduction step. Thioredoxin is the hydrogen donor.

In the red cell, peroxiredoxin-2 activates the Gárdos channel, a charybdotoxin-sensitive Ca^{2+}-dependent K^+ channel, which leads to the loss of K^+ and water.[677] This activation is associated with increased Ca^{2+}-dependent binding of dimeric peroxiredoxin (calpromotin) to the red cell membrane as a pentamer of the dimers.[414,679] Peroxiredoxin-2 is especially abundant on the red cell membranes of sickle cells,[680] particularly the dense, dehydrated fraction of sickle cells. Thalassemic red cells also contain increased peroxiredoxin-2 but less is bound to the membrane, perhaps because the binding sites on band 3 are blocked by oxidized hemoglobin (hemichromes).[681] Interestingly, peroxiredoxin-2 binds stomatin,[414] a protein that is located in lipid rafts and is mistrafficked in hereditary stomatocytosis (see Chapter 16).

Peroxiredoxin-2 is extremely efficient at scavenging hydrogen peroxide (H_2O_2).[682] It can rapidly detect and remove even the small amounts generated endogenously by hemoglobin autooxidation. In the process the enzyme is oxidized to a disulfide-linked homodimer. Because there is very little thioredoxin reductase activity in red cells, the oxidized enzyme is recycled slowly. However, the concentration of peroxiredoxin-2 is high enough to competently protect the red cell against low concentrations of H_2O_2. Mice lacking peroxiredoxin-2 have a hemolytic anemia that appears spontaneously by about 2 weeks of age and is characterized by Heinz bodies, burrs, spherocytes, and dense red cells.[683,684]

Peroxiredoxin-1

Despite its low concentration, peroxiredoxin-1 also seems to play an important oxidant-protective role in the red cell. Mice with a Prdx1 knockout develop a severe oxidant-type hemolytic anemia beginning at about 9 months of age and later develop several types of cancer.[685] The anemia features reactive oxygen species, protein oxidation, hemoglobin instability, and Heinz bodies.

ORGANIZATION OF THE MEMBRANE SKELETON

Models of the membrane skeleton, such as that shown in Figure 15-6, have existed, with increasing complexity, since 1979.[686] Current models* all have three major features: (1) a network of spectrin interconnecting short F-actin filaments (protofilaments) and associated proteins with the aid of protein 4.1R, which is attached to (2) a complex of ankyrin linked to band 3 tetramers and other associated proteins (the "ankyrin complex," Table 15-3), and (3) a complex of proteins linking the actin junctions to the overlying lipid bilayer (the "actin junctional complex," Table 15-4). Fowler has recently published a superlative review of this topic.[606a]

Spectrin/Actin/Protein 4.1R Membrane Skeleton

- Electron micrographs of spread membrane skeletons show a roughly hexagonal network of spectrin tetramers and some hexamers interconnecting F-actin protofilaments (see Fig. 15-16).[464,509,510]

Spectrin (α/β)‡	Heterodimer	2	6	Spectrin, ankyrin, protein 4.1R, protein 4.2, actin, adducin, dematin, Lu/BCAM

CAII, Carbonic anhydrase II; *CAIV,* carbonic anhydrase IV; *G3PD,* glyceraldehyde-3-phosphate dehydrogenase; *Glut1,* glucose transporter 1; *GPA,* glycophorin A; *GPB,* glycophorin B; *LDH,* lactic dehydrogenase; *Lu/BCAM,* Lutheran antigen/BCAM protein; *LW,* Landsteiner-Wiener glycoprotein; *PFK,* phosphofructokinase; *PK,* pyruvate kinase; *PRDX2,* peroxiredoxin 2; *RhAG,* Rh-associated glycoprotein; *Unk,* unknown.

*G3PD, PFK, and aldolase bind to band 3 as a glycolytic enzyme complex, but there are too few molecules of each to have one such complex per ankyrin complex. Similarly the amounts of CD47 and LW are much less than stoichiometric, so only some ankyrin complexes contain these proteins.

†There are three ankyrin complexes per unit cell (i.e., six complexes, each shared with two adjacent cells).

‡The spectrin dimers in the ankyrin complex are shared with the actin junctional complex.

- There is one double-helical tropomyosin heterodimer containing seven actin-binding sites attached to each F-actin strand,[156] one adducin heterodimer capping the fast-growing end of the actin,[589] and two tropomodulin monomers capping the slow-growing end.[607]
- The numbers of adducins and tropomodulins (see Table 15-2) indicate that there are 30,000 to 40,000 actin protofilaments per red cell. This translates to six to eight G-actins in each of the double-helical F-actin strands. A two-stranded protofilament seven actins long would be approximately 37 nm, which is what is seen in vivo (see Fig. 15-16),[425,464,509,510] and is also the length of a tropomyosin molecule.
- Forty thousand protofilaments also corresponds with the numbers of spectrins and proteins 4.1R (240,000) if six of each bind per actin filament.
- Because the red cell surface area[15] is approximately 140 μm^2, the 40,000 hexagonal unit cells each cover 3,500 nm^2. This means spectrin dimers are only about 32 nm long in vivo (Fig. 15-24, *A*), which is only one third of their contour length (100 nm) in stretched skeletons or in vitro after extraction from the membrane.
- It is not certain how spectrin folds in vivo, but the best data[425] indicate the two spectrin chains are tightly coiled about each other and are relatively straight. They stretch and retract by changing their pitch and diameter (see Fig. 15-15).
- Spectrin heterodimers must occupy two actin subunits when bound, either directly or due to steric interference. Details of the attachment of spectrin to F-actin and where protein 4.1R fits in the interaction are not known. Spectrin is likely to mimic other spectrin-family proteins such as α actinin (see Fig. 15-17),[487,688] dystrophin,[689] utrophin,[690] fimbrin,[691] and plectin,[692] but these proteins interact with F-actin in more than one way[688,690] and do not require protein 4.1R. In the case of spectrin, there must be some flexibility in the linkage or in spectrin because binding sites must wind around the helical actin filaments but the spectrin skeleton and its actin protofilaments[515] are planar and parallel to the membrane.

Ankyrin Complex

- Only one ankyrin binds to the two neighboring ankyrin sites on a spectrin tetramer, presumably because of steric interference.
- Two band 3 dimers bind to two different sites on the membrane-binding domain of ankyrin,[623,628] but it is not clear whether these are a true band 3 tetramer or two unconnected dimers.
- Band 3 is required for protein 4.2 expression on the membrane,[220] and the two proteins bind in vitro, but the binding site on band 3 and the stoichiometry (1:1) are not well defined.
- A separate Rh complex also binds to ankyrin[332] and probably to band 3. It contains a trimer of RhAG,

TABLE 15-4 Composition of the Actin Junctional Complex

Protein	Oligomeric State	No. of Oligomers in Complex and Unit Cell[*]	Interactions in Mature Erythrocyte Membranes
Actin	Protofilament (14 monomers)	1	Spectrin, protein 4.1R, tropomyosin, tropomodulin, adducin, chorein
Adducin (α/β)	Heterodimer	1	Actin, spectrin, band 3, Glut1, stomatin, NHE1, chorein

Tropomyosin	Homodimer	2	Actin

CAII, Carbonic anhydrase II; *CAIV,* carbonic anhydrase IV; *DARC,* Duffy antigen /chemokine receptor; *G3PD,* glyceraldehyde-3-phosphate dehydrogenase; *Glut1,* glucose transporter 1; *GPA,* glycophorin A; *GPC/D,* glycophorin C/D; *LDH,* lactic dehydrogenase; *Lu/BCAM,* Lutheran antigen/BCAM protein; *NHE1,* Na^+/H^+ exchanger 1; *PFK,* phosphofructokinase; *PK,* pyruvate kinase; *PRDX2,* peroxiredoxin 2; *Unk,* unknown.

[*] There is one actin junctional complex per unit cell.

[†] G3PD, PFK, and aldolase bind to band 3 as a glycolytic enzyme complex, but there are too few molecules of each to have one such complex in every actin junctional complex. Similarly the amounts of Kell and Kx are less than stoichiometric, so only some junctional complexes contain these proteins.

[‡] As noted in the text, it is not clear whether one band 3 associates with the actin junctional complex, which would fit with the stoichiometry of band 3-binding proteins like adducin, or whether as many as six band 3 molecules are present, which would fit with the stoichiometry of band 3-binding proteins like protein 4.1R.

[§] The spectrin dimers in the actin junctional complex are shared with the ankyrin complex.

RhD, and RhCE[330] and probably GPB.[287] CD47 and the LW are trace proteins that are sometimes part of this complex[330] (about 1 in 9 complexes contain CD47, about 1 in 30 contain LW). CD47 is linked to protein 4.2 and to the Rh proteins.[384-386]

- Similarly, some ankyrin complexes contain the glycolytic metabolon,[186] described earlier, bound to band 3, but there are only 6000 copies of the least prevalent member, phosphofructokinase,[179] so if the metabolon has constant stoichiometry, there can only be about 1 for each 20 ankyrin complexes.
- The ankyrin complexes are each shared with two unit cells so there are only three per unit cell (see Fig. 15-24, *B*).

Actin Junctional Complex

- This complex is less well defined. It seems clear that, on average, six spectrins and six proteins 4.1R bind per actin, and there is enough band 3, GPA, GPC/D, and probably enough glucose transporter-1, and stomatin to supply six complexes per actin filament. But there is only one copy of adducin per actin

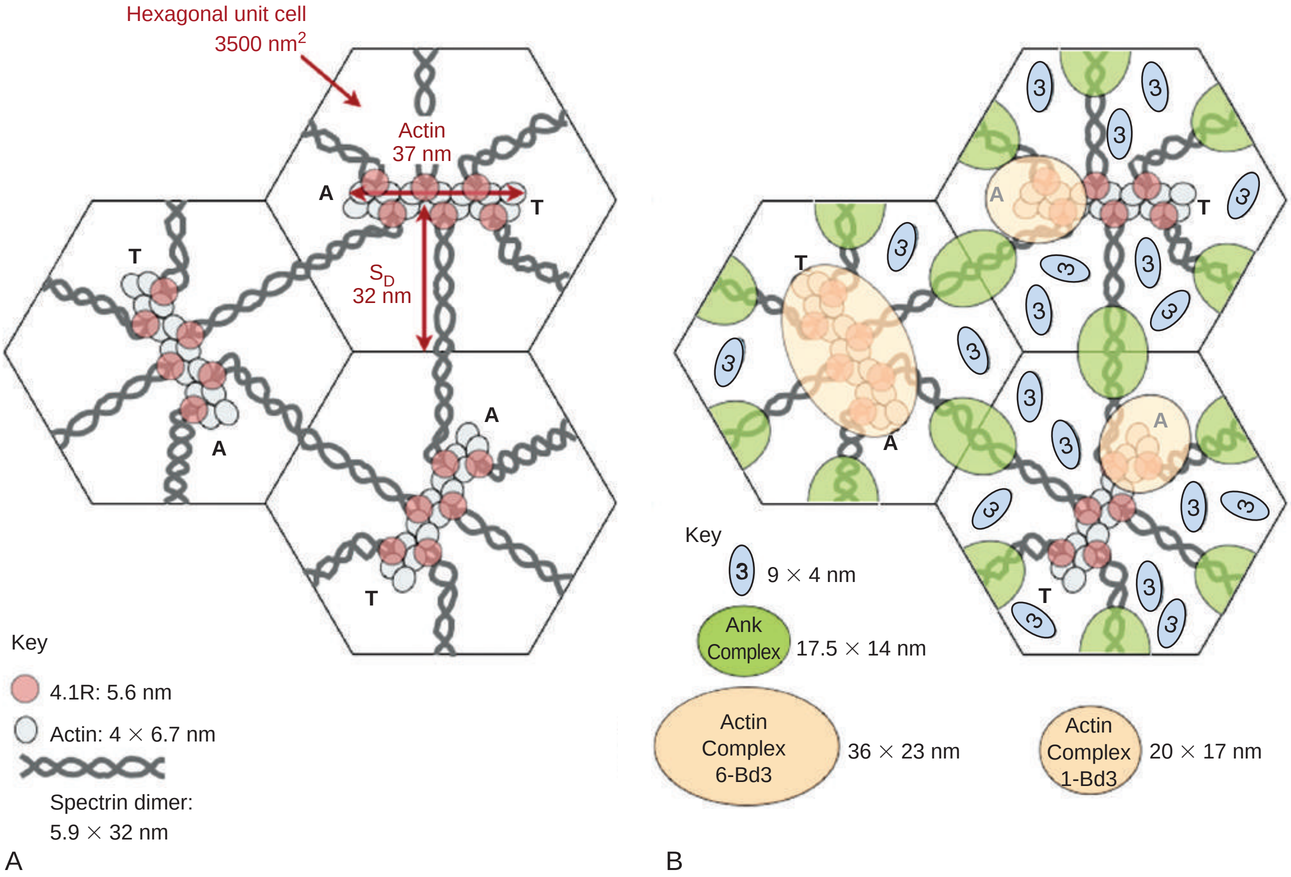

Figure 15-24 Scale model of the membrane skeleton unit cell. **A,** The membrane skeleton is a hexagonal lattice centered around about 40,000 F-actin protofilaments. Each 37-nm protofilament is capped by adducin *(A)* and tropomodulin *(T)* and contains about 14 G-actin subunits. The red cell surface area is about 140 µm^2, so each hexagonal unit cell is 3500 nm^2. Simple calculations show the average length of a spectrin dimer must be about 32 nm, which is one third of its length when fully stretched. The folding of the spectrin chains in this shortened configuration is not known for certain, but the best data indicate that they are relatively straight, are coiled about each other, and expand and contract by changing their pitch and diameter (see Fig. 15-15). **B,** Burton and Bruce[421] have modeled the structures of red cell membrane proteins and conclude that the cross-sectional area of the ankyrin complex *(green ovals)* is approximately 17.5 nm × 14 nm if the proteins are closely packed. The cross-sectional area of the actin junctional complex is about 20 nm × 17 nm if it only contains a single band 3 dimer *(small tan ovals)*. Such a complex would likely lie toward the end of the actin protofilament where adducin resides. This is shown in the two unit cells on the right. Alternatively, if the actin junctional complex contains six band 3 dimers and all six 4.1R proteins, it would probably be more centered and approximate the *large tan oval* in the unit cell on the left. In either arrangement it is likely the ankyrin complex and actin junctional complex would be close to each other and probably often touch, particularly during red cell deformation. Band 3 dimers that are not associated with either the ankyrin or actin junctional complexes *(small blue ovals)* diffuse in the lipid bilayer within the spectrin corrals. There will be three to eight of these per unit cell depending on the number of band 3 dimers in the actin junctional complex.

filament and only three copies of dematin if it is a monomer as recent studies indicate (see Table 15-4). Similarly, whereas protein 4.1R, GPC/D, and protein p55 are usually pictured as a three-part complex (see Fig. 15-19), there is only enough p55 for one copy per actin filament if it is a dimer, as some data suggest. And there is only about one copy of protein 4.2 available if 240,000 copies (one per band 3 dimer) are tied up in the ankyrin complex as is generally believed.

- Because the glucose transport channel (Glut1) binds to adducin,[420] dematin,[420] and stomatin,[413] and perhaps to band 3,[421] there is at least one and possible more copies of Glut1 and stomatin in the actin junctional complex.
- There is also evidence that the complex contains enzymes in the glycolytic metabolon[186] and the blood group proteins Kx/Kell and DARC,[542] although the amounts of these proteins are insufficient for even one copy per complex.
- It is unclear at the moment whether the actin junctional complex contains only a single band 3 dimer, interacting with just one or two of the six spectrin/protein 4.1R dyads or whether it is a larger complex containing three to six band 3 dimers that interact with all the spectrins and proteins 4.1R. In the latter case only a subset of the band 3 molegules would also bind to adducin. Both possibilities are depicted in Figure 15-24.
- In either case, one of the interesting and greatly underappreciated facts is that the *ankyrin and actin junctional complexes are quite close to each other in situ on the membrane and must often come in contact,* especially during red cell deformation, but

perhaps even when the cell is at rest. This raises the interesting possibility that proteins such as band 3, proteins 4.1R and 4.2, and adducin, which have binding partners in both complexes, may sometimes switch allegiances. Because some proteins compete for the same binding sites—protein 4.1R displaces ankyrin from band 3, for example—this could be a regulatory process.

Distribution of Band 3

- There are about 1.2 million band 3 molecules per red cell (average of many published measurements). Forty percent of the total are bound by ankyrin because each ankyrin binds two band 3 dimers.
- Depending on whether the actin junctional complex contains one or six band 3 dimers, an additional 7% to 40% of the band 3 dimers are located there.
- The remaining band 3 dimers (20% to 53%) are believed to be diffusing freely in the lipid bilayer, constrained for the most part by the boundaries of the spectrin corrals (see Fig. 15-24), although occasionally hopping from one corral to a neighboring one.[693] This is within the range of 25% freely diffusing band 3 measured in normal red cells using fluorescence-imaged microdeformation[384] and 46% measured using single particle tracking methods.[693]

Modulation of Membrane Skeletal Structure

Red cell membrane proteins are subject to a large number of posttranslational modifications or other regulatory effects: phosphorylation, fatty acid acylation, methylation, glycosylation, deamidation, ubiquitination, calpain cleavage, polyphosphoinositide and calmodulin regulation, oxidation, and modification by polyanions. A detailed discussion of all these pathways is beyond the scope of this chapter. A thorough review was published some years ago.[115] Table 15-5 lists the better characterized modifications and their effects.

Phosphorylation

In general, most of the membrane skeleton proteins are phosphorylated by one or more protein kinases—including band 3, protein 4.1R, ankyrin, α and β adducin, and dematin—and the added phosphate interferes with one or more protein interactions. Specifically, phosphorylation weakens band 3 binding to glycolytic enzymes, hemoglobin, and ankyrin; ankyrin binding to band 3; protein 4.1R binding to spectrin, band 3, and GPC; adducin capping actin and binding to spectrin; and the ability of dematin to bundle actin and promote spectrin-actin binding (see Table 15-5).

Ca^{2+}-Calmodulin

Similarly, Ca^{2+} in collaboration with calmodulin (CaM) influences the functions of several proteins (see Table 15-5) and these seem to be meaningful effects because physiologic concentrations of CaM, sealed in red cell ghosts, destabilize membranes in the presence, but not absence, of micromolar concentrations of Ca^{2+}.[695] The effects of Ca^{2+} begin at 10^{-6} to 10^{-7} M, which is relatively low, but still higher than the free Ca^{2+} concentration in the erythrocyte (20 to 50 nM[139,696]). Protein 4.1R, adducin, and α-spectrin functions are regulated by CaM. Ca^{2+}-CaM reduces the affinity of protein 4.1R for band 3, GPC, p55, and CD44, and it reduces adducin binding to F-actin and adducin-mediated enhancement of spectrin-actin binding.

Free Ca^{2+}

Among other things, free Ca^{2+} augments the binding of protein 4.2 to the EF hand domain. Another effect of free Ca^{2+} involves calpain, one of a family of Ca^{2+}-stimulated neutral proteases that are present in red cells[115] and other tissues. Susceptible membrane substrates include adducin, ankyrin, protein 4.1R, and, to a lesser extent, spectrin and band 3. The Ca^{2+}-induced K^+-channel (Gárdos channel),[697] described later in the chapter, is also triggered by Ca^{2+}. This unidirectional channel causes K^+ and water loss, producing cellular dehydration. Finally, Ca^{2+} also induces phospholipid scrambling, as discussed earlier in the chapter.

The mechanisms of Ca^{2+} entry into red cells are not well-understood, but investigations implicate the mechanosensitive Piezo1 cation channel and another nonselective cation channel called TRPC6 (both discussed later).

Polyanions

Physiologic concentrations of organic polyanions such as 2,3-DPG and ATP weaken and dissociate the membrane skeleton[698,699] and increase the lateral mobility of band 3 in ghosts.[700] Because hemoglobin F does not bind 2,3-DPG, free 2,3-DPG concentrations are much higher in fetal red cells. This may contribute to the increased severity of hereditary elliptocytosis during infancy in some patients (see Chapter 16).[699]

Biogenesis of the Membrane Skeleton

Surveys of the expression of membrane proteins during red cell development in mice[168] distinguish two patterns. Proteins such as band 3, ankyrin, RhAG, dematin, and the glycophorins are expressed early in erythropoiesis and often decline by the reticulocyte stage, whereas proteins such as spectrin, adducin, and proteins 4.1R, 4.2, and p55 are increasingly expressed throughout erythroid development (Fig. 15-25). Actin expression is nearly constant.[168]

Not much is known about how the membrane skeleton is put together in erythroblasts. Measurements of the sequential assembly of membrane protein complexes using modern proteomic techniques are badly needed. Fortunately, the necessary techniques for isolating pure populations of human erythroblasts are now available.[701] Early studies suggested that spectrin and ankyrin were made early, turned over rapidly, and did not assemble into a stable skeleton until band 3 and protein 4.1R were synthesized.[702,703] However, analyses show that the diffusion of band 3 in the membrane is gradually restricted throughout erythropoiesis and is not suddenly limited by rapid, coordinated assembly of the membrane skeleton.[704] In addition the early observations do not fit with data showing that band 3 is expressed before spectrin (see Fig. 15-25) or with the observation that mice lacking all band 3 assemble a functional, and nearly structurally normal spectrin-based membrane skeleton.[220] Clearly

TABLE 15-5 Regulation of Membrane Skeleton Proteins

Protein	Modification	Location	Effect	References
α Spectrin	Ca^{2+} binding	EF hands	Increases binding of protein 4.2.	486
	Calmodulin	EF hands	Blocks Ca^{2+} effect on 4.2 binding.	486
	Ubiquitination	α-Spectrin C-terminus	Impairs association with F-actin junctional complex.	507
β Spectrin	Phosphorylation	CKI: T2110, S2117, S2123, S2125, S2128	Phosphorylated by CKI. No effect on spectrin interactions in vitro but in vivo increased phosphorylation decreases RBC membrane stability.	454, 499, 500, 502, 503
Band 3	Phosphorylation	TK: Y8, Y21, Y359, Y904	Phosphorylated by $p72^{syk}$ and Lyn kinases. Blocks binding of glycolytic enzymes, and hemoglobin and increases glycolysis. Weakens ankyrin binding.	194, 224-227, 694
Ankyrin	Phosphorylation	Unknown	Phosphorylated by CKI and CKII. Sites unknown. Abolishes ankyrin preference to bind to spectrin tetramers instead of dimers. Decreases binding to band 3.	631, 638, 640, 641
	Hydroxylation	Membrane domain	FIH catalyzed. Modifies Asn residues in several ankyrin repeats. Stabilizes membrane domain and inhibits band 3 binding.	642
Protein 4.1R	Phosphorylation	PKC: S312 PKA: S331 & S467 TK: Y418	Phosphorylated by PKA, PKC, and a TK. Each decreases spectrin binding. PKC also blocks the interaction with band 3 and GPC.	115, 550, 553
	Calmodulin	A264-L280	Stabilizes membrane-binding domain.	555
	Ca^{2+}-calmodulin	A181-L197	Reduces affinity of 4.1R for band 3, GPC, p55, NHE1, and CD44.	537, 546, 547, 554
	PIP_2	Unknown	Enhances binding to the CH2 actin-binding domain of β spectrin and to GPC. Inhibits binding to band 3.	473, 558
α Adducin	Phosphorylation of neck region	PKA: S408, S436, S481 RhoK: T455, T480	RhoK enhances interaction of adducin with F-actin. Effect of PKA phosphorylation unknown.	593, 595
α Adducin & β Adducin	Phosphorylation of MARCKS domain	PKA/PKC: S726 (α) and S713 (β)	PKA decreases binding to and enhancement of spectrin-actin interactions. PKC inhibits actin capping and adducin-mediated recruitment of spectrin to actin. PKA or PKC inhibit calmodulin binding.	593, 594
	Ca^{2+}-Calmodulin	MARCKS domain	Reduces adducin binding to F-actin and adducin-mediated enhancement of spectrin-actin binding. Reduces PKA phosphorylation of β adducin and PKC phosphorylation of α and β adducin.	529, 590, 593
Protein 4.2	Myristoylation	G2	Required for membrane localization	673
	Palmitoylation	C203	Enhances binding of protein 4.2 to band 3.	664, 674
	ATP binding	G342-R352	Binds ATP. Function unknown.	601
p55	Palmitoylation	Unknown	Increases binding to membrane. Probably important for stability of lipid rafts.	153
Dematin	Phosphorylation	PKA: S74 PKC: Unk	Phosphorylated by PKA and PKC. PKA abolishes actin-bundling capability. Phosphorylation also abolishes dematin-spectrin binding and dematin ability to increase spectrin-actin interaction.	477, 602-604
Glut1	Stomatin	Unknown	Changes Glut1 to an ascorbic acid transporter.	413
Lu/BCAM	Phosphorylation	Unknown	Required for laminin binding.	366

other membrane sites must bind spectrin and ankyrin in the absence of band 3. The ankyrin/Rh/RhAG, protein 4.1R/p55/GPC, and Glut1/adducin/dematin/actin complexes are good candidates.

Rate-Limiting Steps of Membrane Skeletal Assembly

Spectrin synthesis is highly asymmetric: α-spectrin synthesis exceeds β-spectrin synthesis by at least threefold.[705] Yet the two chains are assembled into the membrane skeleton in equimolar amounts as mixed heterodimers. As a consequence, β spectrin is rate limiting in spectrin assembly. Defects that compromise β-spectrin synthesis are inherited in a dominant pattern, whereas α-spectrin synthetic defects are recessive (see “Hereditary Spherocytosis” in Chapter 16). Individuals missing one complete α-spectrin allele are asymptomatic because sufficient α spectrin is still made to pair with all the β spectrin.

The second rate-limiting step is the availability of ankyrin, which provides the high-affinity binding sites for β spectrin. This is best illustrated by studies of membrane skeletal synthesis in spherocytic mice with ankyrin mutations[653,668] and in a severe form of human hereditary spherocytosis associated with combined deficiency of spectrin and ankyrin.[706] In both disorders ankyrin synthesis is markedly reduced, which leads to decreased assembly of spectrin and ankyrin on the membrane, in spite of normal spectrin synthesis.

Membrane Remodeling During Enucleation and Reticulocyte Maturation

At the orthochromatic erythroblast stage, when membrane biogenesis is nearly complete, the cell membrane undergoes a series of critical remodeling steps. The cell nucleus is isolated by a contractible actin ring, which forms on the cell membrane at the boundary between atoplasm and the nucleus and participates in expelling of the nucleus from the erythroblast. This process requires Rac GTPases and mDia2, one of the formin proteins that nucleate linear actin filaments.[707] Rac1 and Rac2 bind to mDia2 in a GTP-dependent manner, and mDia2 causes the contractile actin ring to form.

During enucleation, the spectrin skeleton, proteins that attach to it, and selected other proteins segregate into the incipient reticulocyte while some surface receptors and presumably excess or unattached membrane proteins cluster in the membrane surrounding the soon to be extruded nucleus and are lost along with the bulk of the endoplasmic reticulum and nuclear proteins (Fig. 15-26, *A*).[708-710] The discarded membrane proteins include part of the band 3, GPC, Glut1, CD44, and stomatin.[536,710] In patients with hereditary spherocytosis due to ankyrin deficiency, GPA and RhAG, which normally partition into the reticulocytes, are also lost.[536] Similarly, in protein 4.1R–deficient red cells, even more GPC is lost with the nucleus.[536]

Further membrane remodeling takes place by exocytosis as the young multilobular reticulocyte attains the biconcave shape (see Fig. 15-26, *B* and *C*).[711-713] This is best studied in the case of transferrin receptors, which enter the reticulocyte by endocytosis and are segregated into vesicles called “exosomes” within large membrane-bounded sacs called multivesicular bodies. These fuse with the plasma membrane, discharging the exosomes and their protein cargo (see Fig. 15-26). The transferrin

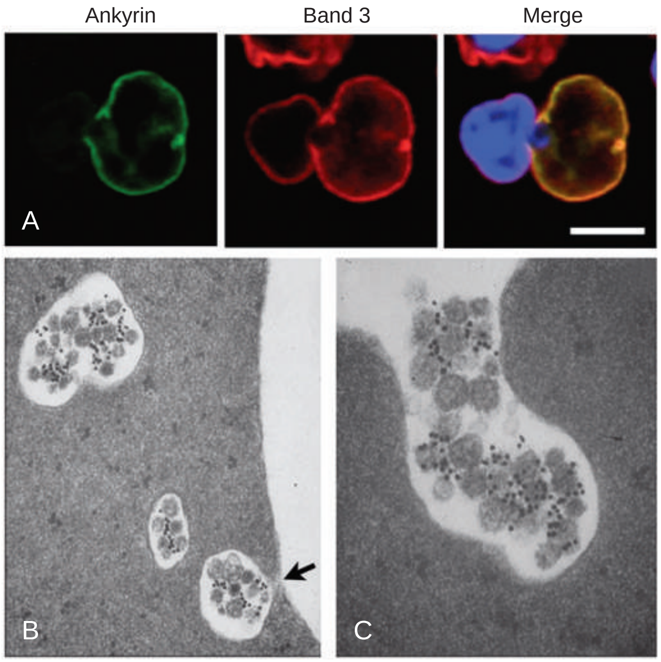

Figure 15-26 Maturation of the reticulocyte membrane. **A,** During enucleation, proteins attached to the membrane skeleton, such as ankyrin, segregate with the incipient reticulocyte, whereas a portion of the unattached membrane proteins, such as band 3, are lost with the nucleus. *Bar* = 5 μM. **B,** As reticulocytes mature, transferrin receptors, labeled with gold-bound antibodies, collect in small vesicles (exosomes) within intracellular sacs called multivesicular bodies, which approach the plasma membrane and begin to fuse *(arrow)*, with eventual release (**C**) of exosomes from the cell. A variety of membrane and cytoplasmic proteins are released by this mechanism. *(**A**, From Bell AJ, Satchwell TJ, Heesom KJ, et al: Protein distribution during human erythroblast enucleation in vitro.* PLoS One *8:e60300, 2013. **B** and **C**, From Johnstone RM: Revisiting the road to the discovery of exosomes.* Blood Cells Mol Dis *34:214–219, 2005.)*

receptor is lost with heat shock protein 70, which binds to the cytoplasmic domain and seems to act as a chaperone.[714] A variety of other membrane proteins are lost by this mechanism, including the Na^+,K^+-ATPase; aquaporin-1; Glut4 glucose transporter; CD47; nucleoside transporter; LFA3; α4β1 integrin, which binds fibronectin; small GTP-binding proteins such as Rab 4p, Rab 5p, and adenosine diphosphate ribosylation factor; GPI-linked lipid raft proteins such as acetylcholinesterase, CD55, and CD59; and other raft proteins such as stomatin and flotillin.[713] Ubiquitination appears to be a signal that directs proteins into the multivesicular bodies via the ESCRT endosomal sorting machinery.[713] Naturally occurring IgM antibodies to Lyso-PC bind the released exosomes, lead to C3 deposition, and are probably involved in exosome clearance.[715]

Cytosolic actin and tubulin are also lost as reticulocytes mature, probably by ubiquitin-proteosome degradation; and in addition to the proteins just mentioned, the amounts of myosin, tropomyosin, NHE-1, LW glycoprotein, GPA, Duffy, and Kell in the membrane are reduced by undefined mechanisms.[716]

Autophagocytosis also plays an important role in removing mitochondria, cytoplasmic organelles, and some membrane receptors. Cholesterol-fed mice that lack the high-density lipoprotein receptor and apoprotein E are anemic with targeted, macrocytic red cells and reticulocytes containing large abnormal autophagolysosomes.[717] The cholesterol-loaded reticulocytes also retain ribosomes and transferrin receptor. Removal of cholesterol, incubation in normolipemic serum, or transfusion into normal recipients leads to expulsion of the autophagolysosomes and reinitiation of reticulocyte maturation.[717] How cholesterol accumulation inhibits reticulocyte maturation remains to be determined.

RED CELL MEMBRANE DEFORMABILITY AND STABILITY

Material Properties

The material properties of the membrane reflect the properties of both the lipid bilayer and the skeleton. During deformation of the red cell membrane, bending is restricted by the incompressibility of the lipid bilayer and is facilitated by rapid translocation of cholesterol from the inner to the outer half of the bilayer.[718] The lipid bilayer cannot expand its surface area more than 3% to 4%. Consequently, when red cells are suspended in hypotonic solutions, such as during osmotic fragility testing, they swell to a spherical shape and then rupture, discharging their hemoglobin into the supernatant.[719]

The membrane skeleton determines both the solid and semisolid properties of the membrane.[720] The solid properties are exemplified by an elastic extension of cells, which completely restore their normal shape after the applied force has been removed. This elastic recovery of the biconcave shape is facilitated by the unique molecular anatomy of the skeletal lattice. In normal red cells individual spectrin molecules are arranged in a quasi-hexagonal array and are twisted in a compact configuration (see Figs. 15-15 and 15-24). The junctional complexes are close to each other and are linked by shortened spectrin tetramers, thus allowing large unidirectional extensions without disruption of the lattice. The skeletal connections are unperturbed during such deformations. On the other hand, application of large or prolonged forces allows the skeletal elements to reorganize and make new connections. This produces a permanent "plastic" deformation (see later). When the force is excessive, membrane fragmentation ensues. An example is the poikilocytosis produced in microangiopathic blood vessels where red cells may adhere to damaged endothelium and be stretched by the vascular torrent or may be "clotheslined" by fibrin strands.[721] After release, many of the cells are either permanently deformed or fragmented.

Cellular and Molecular Determinants of Red Cell Deformability

The need to undergo large deformations is best exemplified in the wall of the splenic sinus where red cells have to "squeeze" through narrow slits between the endothelial cells that line the splenic sinus wall (Fig. 15-27) as the exit the splenic cords and return to the circulation

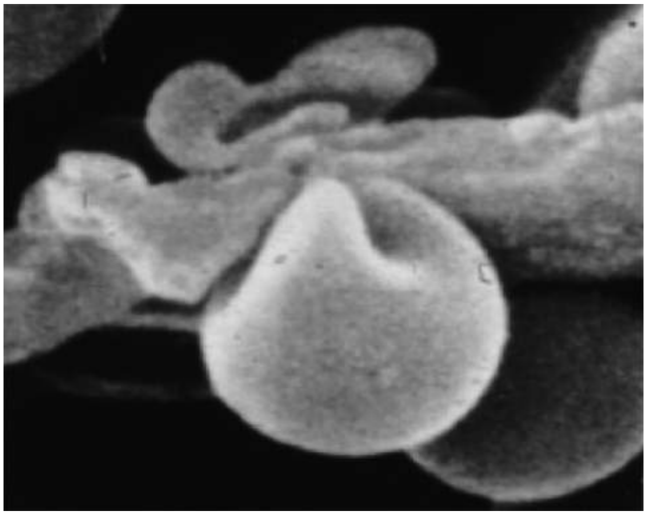

Figure 15-27 Red cell traversing the narrow passage between the endothelial cells separating the splenic cords from the splenic sinuses. Note the marked deformation the cell experiences. *(From Mohandas N, Gallagher PG: Red cell membrane: past, present and future.* Blood *112:3939–3947, 2008.)*

(see discussion of splenic structure and function in Chapter 23). This whole-cell deformability is determined by three factors: (1) cell geometry, that is, a large cell surface-to-volume ratio, which allows cells to undergo large deformations at a constant volume; (2) viscosity of the cell contents, which is principally determined by the properties and the concentration of hemoglobin in the cells; and (3) intrinsic viscoelastic properties of the red cell membrane.[720] Among these factors, the contribution of the surface-to-volume ratio is the most important, as exemplified by the cellular lesion in hereditary spherocytosis. Cellular dehydration, as occurs in hereditary spherocytosis and hereditary xerocytosis (see Chapter 16), sickle cell disease (see Chapter 20), and hemoglobin C disease (see Chapters 19 and 20) is also important because the viscosity of hemoglobin rises extremely rapidly once the concentration of hemoglobin exceeds the physiologic range (Fig. 15-28). Because 97% of the protein in the red cell is hemoglobin,[722] its viscosity has a profound effect on the viscosity of the red cell as a whole.

On the other hand, the intrinsic deformability of the red cell membrane has a relatively small effect on red cell survival. This is best illustrated by the red cell membrane properties of Southeast Asian ovalocytes (SAO; see Chapter 16), which carry a mutant band 3 protein. Both the intact SAO red cells and their membranes are extremely rigid,[723] yet the SAO red cells have a normal or nearly normal survival in vivo.

Some integral proteins may also influence membrane deformability. For example, treatment of red cells by antibodies against GPA, including their Fab fragments, leads to reduced deformability via transmembrane signaling. Red cells that lack the cytoplasmic domain of GPA (e.g., Miltenberger V red cells) are not influenced by such treatment.[262,282]

Membrane Structural Integrity and Fragmentation

The skeleton is the principal determinant of membrane stability. As noted earlier, it is possible to manipulate the proportion of spectrin dimers and tetramers in situ by exposing ghosts to temperatures and salt concentrations that favor or discourage self-association. Ghosts enriched in spectrin dimers are strikingly fragile.[459] Similarly, hereditary elliptocytosis and pyropoikilocytosis is usually due to α- or β-spectrin mutations that weaken spectrin self-association (see later sections). In such cells the quasi-hexagonal skeletal lattice is disrupted,[724] which in severe cases leads to red cell fragmentation and poikilocytosis.

Lipid Bilayer Loss and Microvesiculation. The fragile lipid bilayer is stabilized both by the underlying membrane skeleton and the transmembrane proteins. In vitro, the bilayer can be uncoupled from the skeleton at the tips of spiculated red cells by force or by various treatments (Fig. 15-29).[725,726] The lipids are released in the form of microvesicles that contain integral proteins but lack skeletal components.[726] Such loss of membrane material may underlie the surface area deficiency of red cells in hereditary spherocytosis[727] or red cells subjected to prolonged storage[728,729] or ATP depletion.[730] Aggregation of the band 3–containing intramembrane particles in the membrane also destabilizes the lipid bilayer.[165] The particle-free regions bleb and release lipid microvesicles.

Plastic Deformation of Red Cells

The role of the membrane skeleton in red cell shape is best illustrated by irreversibly sickled cells or hereditary

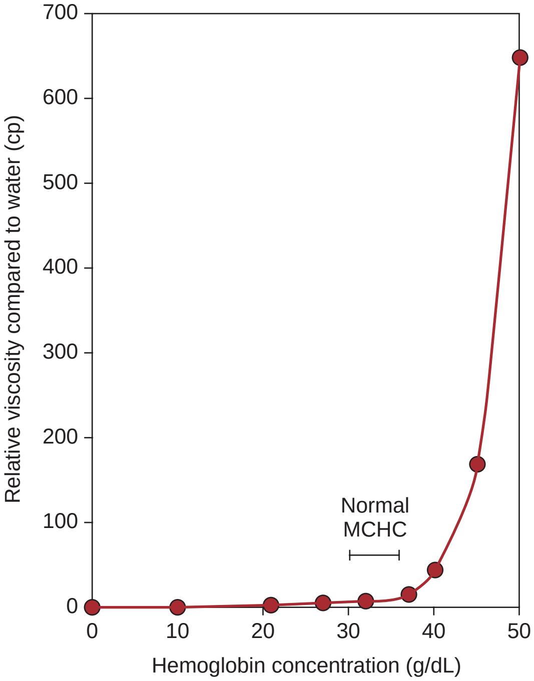

Figure 15-28 Relationship of mean corpuscular hemoglobin concentration *(MCHC)* to the relative viscosity of a hemoglobin solution, where the viscosity of water is 1 centipoise *(cp)*. Note that red cells rapidly become extremely rigid at MCHC values greater than 40 g/dL.

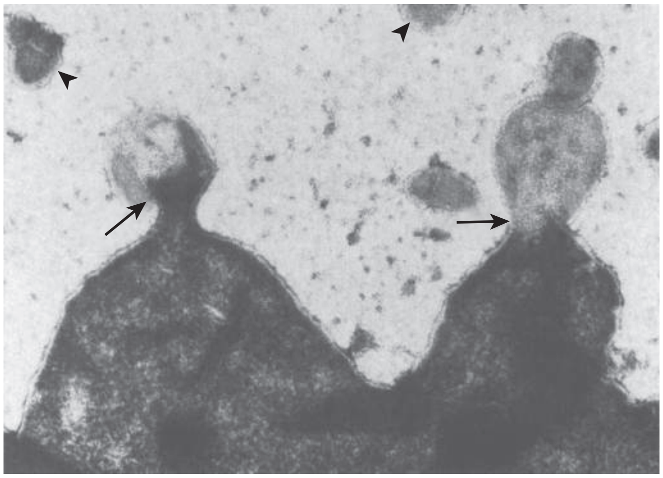

Figure 15-29 Microvesiculation. Red cell ghosts treated with hypertonic saline develop spicules. At the end of the spicules the lipid bilayer often separates from the underlying membrane skeleton. The *arrows* point to the boundary between the skeleton *(dark material below)* and the unsupported lipids *(light material above)*, which are unstable and tend to be released as vesicles *(arrowheads)*. A similar process is believed to occur in a variety of disorders associated with spiculation, such as spur cell anemia and hereditary spherocytosis (see Chapter 16).

elliptocytes, in which the abnormal shape is retained in the ghosts and membrane skeletons.[731,732] This process is probably an example of "plastic deformation," the result of prolonged exposure of red cells to deforming forces, when the proteins of the deformed skeleton rearrange and permanently stabilize the cells in the deformed shape (Fig. 15-30).[720] Existing protein-protein contacts disconnect, and new associations form. In hereditary elliptocytosis, shape transformations may be facilitated by the weakened skeletal protein interactions. In vitro, plastic deformation occurs more rapidly in normal red cells with skeletons weakened by exposure to urea.[733]

In addition both normal and abnormal red cell shapes can be stabilized by intermolecular cross-linking of membrane proteins, either owing to a formation of intermolecular disulfide bridges induced by oxidants or by transamidative protein cross-linking catalyzed by a Ca^{2+}-activated cytosolic transglutaminase.[734] These protein modifications are like endogenous fixatives and permanently stabilize cell shape in vitro.

MEMBRANE PERMEABILITY

Normally the red cell membrane is nearly impermeable to monovalent and divalent cations, thereby maintaining a high potassium, low sodium, and very low calcium content. In contrast, the red cell is highly permeable to water and anions, which are readily exchanged by the water channel and the anion exchange protein (band 3) respectively. Glucose is taken up by the two glucose transporters, whereas larger charged molecules, such as ATP and related compounds, do not cross normal red cell membranes.

The major transport pathways in the human red cell membrane can be divided into four categories (Fig. 15-31):

1. Gradient-driven, passive transporters, which include exchangers, such as the anion exchanger (band 3) and Na^+-H^+-exchanger, and the cotransporters, in which the transmembrane movements of more than one solute are coupled in the same direction, such as the K^+-Cl^- cotransporters and the Na^+-K^+-Cl^- cotransporters.
2. Active transporters, such as the ouabain-inhibitable Na^+,K^+-ATPase pump and the Ca^{2+}-ATPase pump.
3. Channels, such as the aquaporin water channel and Kidd urea channel, discussed earlier, and the Piezo1 K^+ channel and the Ca^{2+}-activated K^+-channel (Gárdos channel), discussed later.

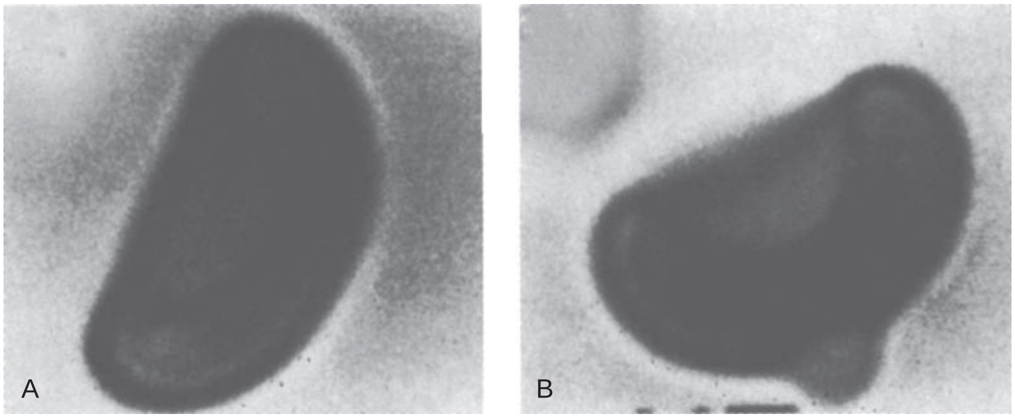

Figure 15-30 Plastic deformation. **A,** Discocytic shape of a red cell at rest in solution. If a nipple of membrane from such a cell is aspirated into a micropipette and released immediately, it snaps back to its original position. However, if the aspirated membrane is deformed for some time, a permanent nipple forms (**B**), as a result of reorganization of the membrane skeleton in the stressed portion of the membrane. This semisolid behavior is called "plastic deformation" and is believed to be responsible for the irregular shape of poikilocytes, especially in diseases such as hereditary pyropoikilocytosis, in which skeletal reorganization is fostered by genetically weakened skeletal interconnections (see Chapter 16). *(From Mohandas N, Chasis JA: Red cell deformability, membrane material properties, and shape: regulation by transmembrane, skeletal, and cytosolic proteins and lipids.* Semin Hematol *30:171-192, 1993.)*

Figure 15-31 Major red cell membrane channels, active transporters, gradient-driven passive transporters, and passive permeability pathways.

4. The passive cation "leak" pathways, which allow Na^+ and K^+ to move in the direction of their concentration gradients.

A detailed review of these pathways is beyond the scope of this chapter. The interested reader is referred to several reviews.[146,696,735]

An important feature of the normal red cell is its ability to maintain a constant volume. One of the very intriguing, yet unanswered, questions is how cells "sense" changes in cell volume and activate appropriate volume regulatory pathways.

Membrane Pumps

To maintain low intracellular concentrations of sodium and calcium and a high potassium concentration, the membrane is endowed with two cation pumps, both utilizing intracellular ATP as an energy source.

Na^+,K^+-ATPase Pump

This well-known, ouabain-inhibitable pump contains a catalytic α-subunit, a β-subunit that interacts with the membrane skeleton, and a small modulatory γ-subunit. The protein extrudes sodium and takes up potassium, with a stoichiometry of three Na^+ ions pumped outward for two K^+ ions pumped inward. This exactly balances the normal passive leaks (Na^+ influx = 1.0 to 2.0 mEq/liters of red blood cells [LRBC]/hr; K^+ efflux = 0.8 to 1.5 mEq/LRBC/hr). The enzyme is activated by intracellular Na^+ (K_m = 25 mM) and extracellular K^+ (K_m = 2.5 mM).[736] Because plasma K^+ is high enough to saturate the extracellular K^+ site, Na^+ and K^+ transport is primarily regulated by increases in red cell Na^+ concentration and cell K^+ losses are rectified only if there is a concomitant Na^+ gain to stimulate active transport. Even then the ratio between the inward Na^+ leak and outward K^+ leak must not be less than the physiologic ratio of 3:2. At lower ratios, the Na^+,K^+-ATPase pump, driven by the Na^+ leak and internal Na^+ concentration will not balance the leaks and will actually exacerbate K^+ loss.[737,738] Consequently, conditions in which K^+ loss approaches or exceeds Na^+ gain lead to irreversible K^+ depletion and cell dehydration.

Ca^{2+}-ATPase Pump

This calmodulin and phosphorylation-activated, Mg^{2+}-dependent protein extrudes Ca^{2+} and maintains a very low intracellular free Ca^{2+} concentration (~20 to 50 nM).[139,696] It protects red cells from the multiple deleterious effects of free Ca^{2+} (echinocytosis, membrane vesiculation, calpain and transglutaminase activation, membrane proteolysis, and cell dehydration), described elsewhere in the chapter. Two of the multiple Ca^{2+}-ATPases are detectable in the red cell (Ca^{2+}-ATPase-1 and Ca^{2+}-ATPase-4).[168] Ca^{2+} extrusion is balanced by H^+ influx.

Transport Pathways Leading to Cellular Dehydration

Several pathways exert a critical volume regulatory effect that can lead to red cell dehydration and destruction. In all cases these pathways lead, directly or indirectly, to a net loss of cations, primarily K^+, which is accompanied by water.

K^+,Cl^- Cotransporter

This typical carrier-mediated cotransport pathway is particularly active in reticulocytes. It is activated by cell swelling, acidification, depletion of intracellular Mg^{2+}, thiol oxidation, and especially by erythrocyte oxygenation, which increases its transport activity about 20-fold.[739] Because band 3 is the only known binding site for deoxyhemoglobin on the membrane, and because a covalent inhibitor of band 3 anion exchange also inhibits the K^+-Cl^- cotransporter,[740] it is likely the K^+-Cl^- cotransporter associates with band 3 to facilitate this O_2-dependent regulation. K^+-Cl^- cotransporter function is increased in sickle red cells and hemoglobin C erythrocytes, accounting, in part, for cellular dehydration of these cells.[741,742]

Gárdos Channel

The second transporter is the Gárdos channel, also called the SK4 or KCa3.1 or KCNN4 channel. The pathway is not active in red cells under normal conditions. It opens and allows K^+ and water loss when intracellular Ca^{2+} rises.[697,743-745] A Ca^{2+} concentration of 0.3 to 2 μM is required for half-maximal activation of the channel. In T lymphocytes and presumably erythrocytes, KCNN4 is also activated by phosphatidylinositol-3-phosphate, which recruits a nucleoside diphosphate kinase-B (gene name *NME2*) that phosphorylates KCNN4 on His358 in the C-terminal region.[746] The channel is inhibited by insect toxins, such as charybdotoxin, and by clotrimazole and other imidazole antimycotics.[146] In sickle cells, the combination of the Gárdos pathway, the K^+-Cl^- cotransporter, and probably the Piezo1 channel (see next section) account for the net loss of K^+ and water, leading to cellular dehydration.

Piezo Channels

The two Piezo proteins, Piezo1 and Piezo2, are very large, widely distributed proteins. They form huge multimeric cation channels, with 120 to 160 transmembrane segments, that are triggered by mechanical distortion of the membrane.[747,748] The channels are nonselective: Na^+, K^+, Ca^{2+}, and Mg^{2+} are all permeable, with a slight preference for Ca^{2+}.[747] Piezo proteins are involved in pain sensing[747] and perhaps in other mechanical sensations such as hearing and touch. The presence of Piezo1 in the red blood cell membrane suggests the channel may also be involved in homeostatic adjustments to changes in volume, responding to membrane stretch. Piezo1 is defective in hereditary xerocytosis (see Chapter 16). Mutations in the protein are present in all 22 families in which sequencing is reported.

Whereas the Piezo1 channel is permeable to K^+, K^+ loss may also be a secondary consequence of excess Ca^{2+} entry through the channel. It is known that Ca^{2+} enters normal red cells when they are deformed.[749] It is likely that this occurs through Piezo1 and triggers Ca^{2+}-stimulated K^+-loss via the Gárdos channel. Indeed, Piezo1 appears to contribute to the dehydration of sickle cells because sickling increases the membrane permeability to Ca^{2+} and other ions, a process, called P^{sickle}, that requires mechanical deformation.[741,742,750,751] P^{sickle} is inhibited by *Grammastola spatulata* mechanotoxin-4,[752] an inhibitor of Piezo1,[753] and the Gárdos channel is a major contributor to K^+ loss and red cell dehydration in sickle cells.[754]

TRPC6 Channel

The TRPC6 channel is another nonselective cation channel that is believed to mediate Ca^{2+} entry into cells. It is activated by diacylglycerol[755] and by binding of phosphoinositides, especially PIP_3, to a C-terminal segment of the protein.[756] PIP_3 disrupts calmodulin binding to the protein. It is also activated by osmotic shock, ATP or chloride depletion, and oxidative stress.[757] Free Ca^{2+} concentration and the extent of red cell shrinkage and phospholipid scrambling are lower in stressed TRPC6 null red cells than in normal mouse erythrocytes,[757] which suggests this channel is physiologically important and participates in Ca^{2+}-induced red cell dehydration, at least under some conditions.

Other Pathways

As noted earlier, hyperactivity of the Na^+,K^+-ATPase pump, triggered by increased intracellular Na^+, can dehydrate red cells because three Na^+ ions are extruded in exchange for only two K^+ ions.

MEMBRANE CHANGES ASSOCIATED WITH AGING AND SENESCENCE OF RED CELLS

Pleiotropic Effects of Red Cell Aging

The removal of senescent red cells from the circulation is a subject of a long-standing interest and has recently been reviewed.[757a] As discussed in a comprehensive review of the literature published prior to 1988,[758] the concept of red cell senescence is based on results of radioactive labeling of a cohort of reticulocytes and bone marrow erythroblasts. In many species, including humans, the fraction of labeled cells remains constant for a defined time period, followed by a rapid decline of radioactivity, suggesting that the red cells are removed from the circulation in an age-dependent manner. Many techniques have been employed to isolate senescent red cells, including methods based on differences in cell density, osmotic fragility, and cell size.[758] Density separation is most widely used but is imperfect. Red cells exhibit a progressive increase in density as they age in vivo, but not all dense red cells are senescent.[758-760]

In addition to in vitro separation techniques, various in vivo animal models have been employed to study red cell aging.[758] For example, red cells can be labeled with biotin and then removed at defined times with avidin, which complexes tightly to biotin.[761] This is the best technique for obtaining a pure population of old red cells, but it has only been applied to humans recently.[762]

The senescent cells defined by these techniques exhibit numerous membrane abnormalities.[758,759,761] Of note is the loss of potassium and water, leading to cell dehydration and increased cell density, and the loss of surface area, presumably owing to gradual release of membrane microvesicles.[758,763] In addition, membrane proteins and lipids in old red cells are oxidized, as evidenced by high-molecular-weight aggregates containing hemoglobin, spectrin, and band 3,[764] and by adducts of proteins and malonylaldehyde, a product of lipid peroxidation. Red cell aging is also associated with a decline of many red cell enzyme activities and in the activity of certain channels, such as the K^+-Cl^- cotransporter.[762,765] However, red cell ATP concentration is normal[758] and there is no evidence that PS is exposed on the red cell surface.[762] Likewise no major abnormalities have been detected in Ca^{2+} transport and there is no compelling evidence that Ca^{2+} accumulates in senescent cells.[758] Importantly, numerous studies show that IgG accumulates on older red cells[762] and may help trigger the removal of senescent cells (see later).

Red cells stored for transfusion show many of the changes of aged red cells—the so-called "storage lesion." The protein alterations are mostly due to oxidation.[766] Degradation of membrane skeleton proteins is particularly prominent, especially protein 4.2. Cross-linking of α spectrin and β spectrin is also observed.[766] Many other cellular changes occur. The topic is beyond the scope of this chapter but has been reviewed elsewhere.[767]

Senescent Autoantibodies

An Autologous Autoantibody Targets Senescent Red Cells for Destruction by Macrophages. Although some of the alterations described above in old red cells may compromise red cell microcirculatory flow, most do not destroy the cells. Kay and colleagues first showed that senescent red cells have small amounts (a few hundred molecules per cell) of autologous IgG on their surface that target the cells for destruction by macrophages.[768] The topic was recently reviewed.[769] Studies suggest the senescent autoantibody arises from a distinctive subset of B cells, termed B-1, that express CD5.[770] The "senescent cell antigen" target appears to be part of the external surface of band 3 that is normally sequestered but becomes exposed when the molecule aggregates.[191,761,771-776] A few believe the epitope resides on the band 3 carbohydrate.[777,778] Band 3 clusters are seen by immunofluorescence microscopy and detected by biochemical methods in aged normal red cells.[191,772]

Aggregation probably results from cumulative oxidative damage because similar damage, including the binding of autologous IgG, takes place on oxidized red cells or red cells containing Heinz bodies, a product of oxidative denaturation of hemoglobin.[191,772,779-781] Both protein peroxidation and methemoglobin formation are needed for band 3 to cluster.[781a] The senescent cell antigen is also exposed on red cells infected with *P. falciparum*.[782,783] Intramembrane particles, which are mostly band 3, are not reproducibly clustered in cells that bear senescent IgG,[784] but this is probably because the clusters of band 3 are rare enough that they are missed by electron microscopy.

Band 3 autoantibodies also trigger complement deposition on senescent cells,[781,785] which accelerates their removal via CR1 receptors on phagocytes. As noted later, this process may be facilitated by microvesiculation and loss of GPI-linked complement regulatory proteins such as CD55 and CD59 as red cells age.

Although the role of autologous IgG in the destruction of senescent erythrocytes is widely accepted, two observations suggest that other mechanisms must be considered. First, blockade of the Fc portion of autologous "senescent" IgG with protein G fails to inhibit red cell phagocytosis.[786] Second, red cell survival is the same in agammaglobulinemic mice as in controls.[786] However, the latter data may not apply to humans, because the removal of mouse red cells from the circulation is random.[758]

Red cells uniquely express the LW blood group antigen or ICAM-4, which interacts with various β2 integrins, including CD11c/CD18 on macrophages. Antibodies to either component inhibit erythrophagocytosis and removal of senescent red cells, suggesting that this interaction contributes to the process.[787,788]

Vesiculation and Microparticle Formation

Blood microparticles or "blood dust" are small, membrane-derived vesicles of less than 1 μm released into the blood by endothelial cells, platelets, white blood cells, and red cells. They are believed to be involved in processes as diverse as inflammation, hemostasis, apoptosis, and vascular and immune function,[789] although it is hard to prove that they play a pathologically important role in any of these processes in vivo.

Microvesiculation occurs during reticulocyte maturation and to a lesser degree throughout the red cell's life span. It is triggered by damage to the connections between the lipid bilayer and the membrane skeleton and by processes such as shear stress, oxidative damage, complement, and eryptosis (see later). The vesicles display the senescent cell antigen (see earlier) as well as PS, which is recognized by scavenger receptors.[790] The fact that the vesicles are enriched in removal signals suggests their release may postpone the untimely removal of functional cells by phagocytosis.[791]

Microvesiculation may serve a housekeeping function, cleansing the red cell membrane of damaged proteins. Low and his colleagues find that oxidative cross-linking of band 3 causes the tyrosine kinase Syk to bind and selectively phosphorylate the oxidized protein.[224] This greatly weakens binding of band 3 and ankyrin, which in turn promotes band 3 diffusion within the lipid bilayer and collection of the damaged band 3 in clumps and membrane spicules, where it is believed to be lost by vesiculation.[228] Or perhaps it is "pitted" from the red cell membrane by the spleen because pitting may just be the coordinated release of vesicles from the membrane and their simultaneous phagocytosis by reticuloendothelial cells.

Red cell–derived microvesicles are also enriched in GPI-linked proteins, such as CD55 and CD59,[792-794] and in other lipid rafts components. Although the loss of complement defense proteins such as CD55 and CD59 would make older red cells more sensitive to complement attack,[795] there is also evidence that the membrane attack complex, C5b-C9, is actively shed in microvesicles when complement is activated.[796]

CD47 "Don't Eat Me Versus Eat Me" Switch

As noted in the earlier section on CD47, the protein serves as a marker of "self" in the mature red cell, interacting with the inhibitory receptor SIRPα on macrophages and inhibiting phagocytosis via complement and

IgG receptors but not via the scavenger receptor.[387-389] Mouse red cells that lack CD47 are rapidly cleared from the blood by normal splenic macrophages.[390] Old red cells have about 30% less CD47 than young red cells, and there is evidence that this may contribute to removal of aged red cells,[797] although reality must be more complicated because red cells lacking CeEe antigens have a normal life span despite diminished expression of CD47 and red cells lacking protein 4.2 nearly lack CD47 and yet experience only mild hemolysis.

Interestingly, there is recent evidence that a conformational change occurs in the CD47 of aged erythrocytes that causes the CD47 to bind thrombospondin-1. This converts CD47 from a “don’t eat me” to an “eat me” signal and leads to removal of the damaged red cells.[798] The stimulus for the conformational change is unknown, but oxidation seems a likely culprit based on what happens to many membrane proteins during red cell storage.[766] Although this is a very promising avenue of research, much more information is needed to understand whether CD47 really contributes to red cell demise.

Eryptosis

Red Cells May Undergo a Kind of Apoptosis in Response to Oxidative Damage. After an initial report by Bratosin in 2001,[799] a “blizzard” of brief papers, virtually all by Lang and his colleagues, have described a process resembling apoptosis in damaged erythrocytes that they term *eryptosis* and that can be triggered by a menagerie of insults and agents.[800,801] The process seems to be a forme fruste of apoptosis because it is not induced by classic apoptotic agents, such as staurosporine, and because mature red cells lack mitochondria and nuclei.[799] It is characterized[800,801] by decreased red cell volume, membrane blebbing, activation of the protease calpain, and PS exposure at the outer membrane leaflet that leads to phagocytosis by macrophages without cell membrane rupture and to adherence of the eryptotic cells to vascular endothelium.[802] Eryptosis is triggered by oxidative stress, an influx of Ca^{2+} ions, red cell dehydration, osmotic shock, prostaglandin E_2, ATP depletion, and a huge variety of other substances and stimuli[801] and is inhibited by erythropoietin and endothelin-1. It is not clear whether each of these stimuli induces the full panoply of eryptosis or just some of the aspects. At a minimum, eryptosis seems to require red cell shrinkage and externalization of PS.

The process resembles that induced by caspases. Investigations show that mature red cells contain Fas, Fas ligand, Fas-associated death domain, caspase 8, and caspase 3 and that oxidatively stressed cells recapitulate apoptotic events, including translocation of Fas into lipid rafts (see later), formation of a Fas-associated complex, and activation of caspases 8 and 3.[803-805] Activation of Fas is also associated with inhibition of the aminophospholipid translocase (flippase) and activation of the scramblase.[806] Thus exposure of PS in red cells, as in nucleated cells, may often be the consequence of apoptotic pathways. However, caspases are not required for eryptosis after Ca^{2+} entry.[801]

These findings raise the possibility that hemolysis in many conditions may be mediated by eryptosis, especially conditions associated with increased oxidant damage and/or cell dehydration, such as sickle cell anemia, thalassemia, Heinz body hemolytic anemias, hemoglobin CC disease, G6PD deficiency, and hereditary xerocytosis. If this is true, interference with the process should be therapeutic. Suicidal death of red cells may also be a defense mechanism against malaria and other erythrocytic parasites, promoting the clearance of infected cells.[807]

FoxO (Forkhead O) transcription factors regulate the cellular response to oxidative stress,[808,809] and the absence of FoxO3, in particular, leads to a marked decrease in expression of antioxidant enzymes in erythroid precursors and a marked susceptibility of mature red cells to the reactive oxygen species that red cells generate during their daily oxygen-carrying duties or to exogenous oxidants. Similarly, lack of the α_1 isoform of AMP-activated protein kinase found in erythrocytes lowers FoxO3 levels and triggers an oxidant-induced hemolytic anemia.[810] It will be interesting to see whether these red cells also die of eryptosis, as would be predicted from the earlier studies, and whether manipulation of the FoxO pathway can be used to treat anemias characterized by oxidant damage.

Finally, other corrosive processes, such external exposure of PS,[811] Ca^{2+}-induced transamidation,[812] or nonenzymatic glycosylation[813] or carboxymethylation[814,815] of membrane proteins are postulated to contribute to red cell demise, but there is little evidence for these speculations.
